Estimation of the coating/water distribution constant can be performed using Equation (3). The appropriate coating/gas distribution constant can be found by applying techniques discussed above, and the gas/water distribution constant (Henry’s constant) can be obtained from physicochemical tables or can be estimated by the structural unit contribution method.

Some correlations can be used to anticipate trends in SPME coating/water distribution constants for analytes. For example, a number of investigators have reported the correlation between octanol/water distribution constant $K_{ow}$ and $K_{fg}$. This is expected, since $K_{ow}$ is a very general measure of the affinity of compounds for the organic phase. It should be remembered, however, that the trends are valid only for compounds within homologous series, such as aliphatic hydrocarbons, aromatic hydrocarbons or phenols; they should not be used to make comparisons between different classes of compounds, because of different analyte activity coefficients in the polymer.

### 2.1.2 Effect of Extraction Parameters

Thermodynamic theory predicts the effects of modifying certain extraction conditions on partitioning and indicates parameters to control for reproducibility. The theory can be used to optimize the extraction conditions with a minimum number of experiments and to correct for variations in extraction conditions, without the need to repeat calibration tests under the new conditions. For example, SPME analysis of outdoor air may be done at ambient temperatures that can vary significantly. The relationship that predicts the effect of temperature on the amount of analyte extracted allows calibration without the need for extensive experimentation. Extraction conditions that affect $K_{fg}$ include temperature, salting, pH and organic solvent content in water. A brief discussion about the use of extraction parameters in SPME method optimization can be found in the next section.
 ENVIRONMENT: WATER AND WASTE

Figure 3 Graphic representation of the SPME/sample system configuration, with dimensions and parameters labeled as follows: $a$, fiber coating inner radius; $b$, fiber coating outer radius; $L$, fiber coating length; $d$, vial inner radius; $C_f$, analyte concentration in the fiber coating; $D_f$, analyte diffusion coefficient in the fiber coating; $C_s$, analyte concentration in the sample; $D_s$, analyte diffusion coefficient in the sample; $K_{fs}$, analyte distribution coefficient between fiber coating and sample; $K_{fs} = C_f/C_s$.

2.2 Kinetics

The kinetic theory is very useful in optimization of the extraction conditions by identifying “bottlenecks” of SPME and indicates strategies to increase extraction speed. In the discussion below we will limit our consideration to direct extraction (Figure 3).

2.2.1 Perfect Agitation

Let us first consider the case where the liquid or gaseous sample is perfectly agitated. In other words, the sample phase moves very rapidly with respect to the fiber, so that all the analytes present in the sample have access to the fiber coating. In this case, the equilibration time, defined as the time required to extract 95% of the equilibrium amount (Figure 4) of an analyte from the sample, corresponds to Equation (7):

$$t_e = t_{95\%} = \frac{2(b-a)^2}{D_f}$$

Using Equation (7) one can estimate the shortest equilibration time possible for the practical system by substituting appropriate data for the diffusion coefficient of an analyte in the coating ($D_f$) and the fiber coating thickness ($b - a$). For example, the equilibration time for the extraction of benzene from a perfectly stirred aqueous solution with a 100µm PDMS film is expected to be about 20s. Equilibration times close to those predicted for perfectly agitated samples have been obtained experimentally for extraction of analytes from air samples (because of high diffusion coefficients in gas) or when very high sonication power was used to facilitate mass transfer in aqueous samples. However, in practice, there is always a layer of unstirred water around the fiber. A higher stirring rate will result in a thinner water layer around the fiber.

2.2.2 Practical Agitation

Independent of the agitation level, fluid contacting a fiber’s surface is always stationary, and as the distance from the fiber surface increases, the fluid movement gradually increases until it corresponds to bulk flow in the sample. To model mass transport, the gradation in fluid motion and convection of molecules in the space surrounding the fiber surface can be simplified by a zone of a defined thickness in which no convection occurs, and perfect agitation in the bulk of the fluid everywhere else. This static layer zone is called Prandtl boundary layer (see Figure 5). Its thickness, $\delta$, is determined by the agitation conditions and the viscosity of the fluid.

The equilibration time can be estimated for practical cases from Equation (8):

$$t_e = t_{95\%} = \frac{3bK_{fs}(b-a)}{D_s}$$

Figure 4 Mass absorbed versus time from perfectly agitated solution of infinite volume.
analyte’s diffusion coefficient in the sample fluid and $K_a$ is the analyte’s distribution constant between the fiber and the sample. Equation (8) can be used to predict equilibration times when the extraction rate is controlled by the diffusion in the boundary layer. In other words, the extraction time calculated by using Equation (8) must be longer than the corresponding time predicted by Equation (7).

### 2.2.3 Time-average Sampling Using in Tube Solid Phase Microextraction

In addition to the analyte concentration measurement at a well-defined place in space and time, obtained by using the approaches discussed above, an integrating sampling is possible with the SPME device. This is particularly important in field measurements when changes of analyte concentration over time, and place-to-place variations, must often be taken into account.

When the extracting phase is not exposed directly to the sample, but is contained in the protective tubing (needle) without any flow of the sample through it, the extraction occurs by the process of diffusion through the static gas phase present in the needle. The integrating system can consist of an externally coated fiber withdrawn into the needle. This simple geometric arrangement represents a very convenient method which is able to generate a response proportional to the integral of the analyte concentration over time and/or space (when the needle is moved through the space). The only mechanism of analyte transport to the extracting phase is diffusion through the gaseous phase contained in the tubing. During this process, a linear concentration profile is established in the tubing between the small needle opening, characterized by surface area $A$, and the distance $Z$ between the needle opening and the position of the extracting phase. The amount of analyte extracted, $\frac{dn}{dt}$, during time interval, $dt$, can be calculated by considering Fick’s first law of diffusion (Equation 9):

$$dn = AD \frac{dC}{dz} \frac{dt}{Z} = AD \frac{\Delta C(t)}{Z} \frac{dt}{t}$$  \hspace{1cm} (9)$$

where $\Delta C(t)/Z$ is a value of the gradient established in the needle between the needle opening and the position of the extracting phase, $Z$; $\Delta C(t) = C(t) - C_Z$, where $C(t)$ is a time dependent concentration of analyte in the sample in the vicinity of the needle opening, and $C_Z$ the concentration of the analyte in the gas phase in the vicinity of the coating. If $C_Z$ is close to zero for a high coating/gas distribution constant capacity, then: $\Delta C(t) = C(t)$. The concentration of analyte at the coating position in the needle, $C_Z$, will increase with integration time, but it will be kept low compared to the sample concentration because of the presence of the sorbing coating. Therefore the accumulated amount over time can be calculated by Equation (10):

$$n = DZ A \frac{C(t)}{Z} \frac{dt}{t}$$  \hspace{1cm} (10)$$

As expected, the extracted amount of analyte is proportional to the integral of a sample concentration over time, the diffusion coefficient of analytes in the gaseous phase, $D_Z$, the area of the needle opening, $A$, and inversely proportional to the distance of the coating position in respect of the needle opening, $Z$. It should be emphasized that this application of the SPME device is not an equilibrium measurement. Equation (10) is valid only in a situation where the amount of analyte extracted onto the sorbent is a small fraction (below relative standard deviation (RSD) of the measurement, typically 5%) of the equilibrium amount in respect to the lowest concentration in the sample. To extend integration times, the coating can be placed deeper into the needle (larger $Z$), the opening of the needle can be reduced by placing an additional orifice (smaller $A$), or a high-capacity sorbent can be used. The first two solutions will result in a low measurement sensitivity. An increase of sorbent capacity presents a more attractive opportunity. It can be achieved by increasing either the volume of the coating, or its affinity towards the analyte. An increase of the coating volume will require an increase in the size of the device. The optimum approach to increased integration time, is to use sorbents characterized by large coating/gas distribution constants, or derivatization reagent in the sorbent.
3 METHOD DEVELOPMENT

Developing a new SPME method in most cases requires the following steps:

- Selection of fiber coating
- Selection of the derivatization reagent, if required
- Selection of the extraction mode
- Selection of the agitation method
- Selection of separation and/or detection technique
- Optimization of desorption conditions
- Optimization of sample volume
- Determination of the extraction time profile in a pure matrix
- Determination of extraction time
- Calculation of the distribution constant
- Optimization of extraction conditions (pH, salt, temperature)
- Determination of the linear range for pure matrix at optimum extraction conditions
- Selection of the calibration method
- Optimization of the extraction conditions for heterogeneous samples
- Verification of the equilibration time, sensitivity and linear dynamic range for complex samples
- Determination of method precision
- Determination of method detection limit (DL)
- Validation of the method
- Automation of the method

In most cases, not all the steps have to be performed. Knowledge gained from previous experiments, as well as from literature, can often be applied to the problem at hand. Most SPME methods developed to date are used in combination with GC separation and an appropriate detection method. Use in conjunction with HPLC and other techniques should be also considered. Following is the discussion of the particular steps in method development, with main focus on aqueous samples.

3.1 Selection of Fiber Coating

The following coatings are currently (1997) commercially available from Supelco, Inc. (Bellefonte, PA): PDMS of three thicknesses: 7, 30 and 100 µm; 85 µm PA; 65 µm poly(dimethylsiloxane)/divinylbenzene (PDMS/DVB); 60 µm PDMS/DVB optimized for HPLC; 65 µm poly(ethylene glycol)/divinylbenzene (Carbowax™/DVB); 65 µm poly(ethylene glycol)/DVB template resin (Carbowax™/TR); and 80 µm PDMS/Carboxen. The PDMS and the PA coatings, still the most widely used, extract analytes by absorption. PDMS is a very viscous liquid, while PA is a low-density solid polymer at room temperature, which allows analytes to diffuse into the coating, but the diffusion coefficients are lower than for PDMS. The remaining coatings are porous polymers, in which DVB or Carboxen porous microspheres are immobilized onto the fiber by using either Carbowax™ or PDMS as the glue to hold them together. These coatings extract analytes by adsorption rather than absorption. The pores in the template DVB polymer are uniform, resulting in less adsorption discrimination as a function of analyte molecular weight. 

Figure 6 presents general guidelines for choosing a coating for a given application. Typically, the chemical nature of the target analyte determines the type of coating used. A simple general rule, “like dissolves like”, applies very well for the liquid coatings. Porous polymer coatings are mostly nonselective. Selection of the coating is based primarily on the polarity and volatility characteristics of the analyte. For example, according to Figure 6, a 100 µm PDMS coating should be used for compounds of high to medium volatility, and low to medium polarity. In general, PDMS is the most useful coating and should be used whenever possible. It is very rugged and able to withstand high injector temperatures, up to about 300 °C. PDMS is a nonpolar phase, thus it extracts nonpolar analytes very well. However, it can also be applied successfully to more polar compounds, particularly after optimizing extraction conditions. An additional advantage of this phase is the possibility of estimating the distribution constants...
for organic compounds from retention parameters on PDMS-coated GC columns (see section 2).

Both the coating thickness and the distribution constant determine the sensitivity of the method and the extraction time. Thick coatings offer increased sensitivity, but require much longer equilibration times. As a general rule, to speed up the sampling process, the thinnest coating offering the sensitivity required should be used. For 100 µm PDMS fibers, the equilibration time in direct aqueous extraction with magnetic stirring is less than 1 hr for compounds characterized by distribution constants, \( K \), lower than \( \sim 10000 \). Thinner PDMS coatings should be considered for compounds of larger \( K \). For more polar compounds, such as phenols, the PA coating is more suitable.

Porous polymer coatings have complementary properties compared to PDMS and PA. They are more suitable for volatile species, the respective distribution ratios typically being larger than for PDMS. Changing the ‘glue’ from PDMS to Carbowax\textsuperscript{™} results in different selectivity towards polar compounds, such as ketones and alcohols. The adsorption times are typically shorter for gaseous samples compared to 100 µm PDMS, since the analytes do not need to diffuse through the liquid polymeric phase.

The TR coating is designed to reduce molecular-weight discrimination for homologs differing in chain length. With regular DVB coatings characterized by nonuniform pore size distribution, the amount of analyte extracted from a solution of a given concentration may vary as a function of the size of a molecule. The TR has uniform pore diameters, therefore it exhibits uniform extraction efficiency.

When a group of analytes of different characteristics (e.g. pesticides) is to be determined by SPME, primary consideration should be given to the analytes that are the most difficult to extract. A coating should be chosen that enables the determination of all the analytes with enough sensitivity. When none of the commercially available coatings meets the requirements, custom coatings can sometimes be prepared. For example, Figure 7 shows the separation of alcohols extracted from unleaded gasoline using a fiber coated with commercially available Nafion\textsuperscript{™} perfluorinated resin.\textsuperscript{(12)} The SPME device also facilitates microsolvent extraction. For example, porous coatings can be used to support organic solvent by placing the fiber into the solvent prior to extraction.\textsuperscript{(13)} Solvent located in the pores extracts analytes from the matrix, when the fiber is placed in contact with a sample.

3.2 Selection of the Derivatization Reagent

Derivatization performed before and/or during extraction can enhance sensitivity and selectivity of both extraction and detection, as well as enabling SPME determination of analytes normally not amenable to analysis by this method, while post-extraction methods can only improve chromatographic behavior and detection. Incorporation of the derivatization step complicates the SPME procedure and therefore should only be considered when necessary. Selective reactions producing specific analogs result in less interference during quantitation. This approach can be used for analyte determination in complex matrices. Sensitivity enhancement can be achieved when the derivatizing reagent contains moieties that enhance detection. For example, the sensitivity of SPME determination of carboxylic acids in water can be greatly improved by using 1-(pentafluorophenyl)diazoethane as the derivatizing reagent.\textsuperscript{(14)} This compound converts carboxylic acids directly in the aqueous matrix to pentafluorophenyl ester derivatives which can be detected by electron capture detection (ECD) with very good sensitivity. Method selectivity is also greatly improved in this way.

In many cases, derivatization reagents designed specifically for liquid extraction procedures can be used in SPME. For example, sodium tetraethylborate was used to enable the analysis of metal ions, including mercury and lead, in water, as well as to perform partial speciation of organometallic compounds by SPME/GC.\textsuperscript{(15,16)}

The most interesting implementation of the derivatization procedure involves the use of doped fibers.
Figure 8 (a) Reconstructed gas chromatography/mass spectrometry (GC/MS) chromatogram illustrating the presence of short-chain fatty acids in a real sewage sample (SPME extraction with PA-coated fiber). Peak assignment: 1, acetic; 2, propionic; 3, isobutyric; 4, butyric; 5, pivalic; 6, isovaleric; 7, valeric; and 8, hexanoic acids. The peaks shown correspond to pyrenylmethyl esters of these acids; (b) An example of the mass fragmentogram and the structure of propionic acid/1-pyrenyldiazomethane (PDAM) ester. (Reproduced by permission from Solid Phase Microextraction: Theory and Practice Pawliszyn © 1997 Wiley-VCH.)

Figure 8 presents a chromatogram obtained by exposing a PA-coated fiber doped with PDAM to the headspace of a sewage sample. All volatile carboxylic acids are detected. Without derivatization, SPME is not capable of extracting sufficient amounts of these acids because no appropriate selective coating exists as of yet. Such an approach results in high sensitivity and is compatible with field analysis requirements, since the derivatizing reagent and the derivatization products are nonvolatile. The doped fibers not only facilitate spot sampling, but can also measure long-term exposure to a given contaminant, since analytes are continuously accumulated onto the fiber until all the reagent is consumed.

### 3.3 Selection of the Extraction Mode

Extraction mode selection is based on the sample matrix composition, analyte volatility, and its affinity to the matrix. For very dirty samples the headspace or fiber protection mode should be selected. For clean matrices, both direct and headspace sampling can be used. The latter is applicable for analytes of medium to high volatility. Headspace extraction is always preferential for volatile analytes because the equilibration times are shorter in this mode compared to direct extraction. Extraction conditions for many compounds, including polar and ionic ones, can be improved by matrix modifications, as described later. Application of headspace SPME can be extended to semivolatile compounds and analytes strongly bound to the matrix by increasing the extraction temperature, also discussed below. Fiber protection should be used only for very dirty samples in cases where neither of the first two modes can be applied. General sampling mode guidelines are presented in Table 1.

### 3.4 Selection of the Agitation Technique

Equilibration times in gaseous samples are short and frequently limited only by the rate of diffusion of the analytes in the coating. A similar situation occurs when analytes characterized by large air/water distribution constants are determined in water by the headspace technique. When the aqueous and gaseous phases are at equilibrium prior to the beginning of the sampling process, most of the analytes are in the headspace. As a result, the extraction times are short even when no agitation is used. However, for aqueous samples, agitation is required in most cases to facilitate mass transport between the bulk of the aqueous sample and the fiber. Table 2 summarizes the properties of several agitation methods which have been tested with SPME.

Care must be taken when using magnetic stirring to ensure that the rotational speed of the stirring bar is constant and that the base plate does not change its temperature during stirring. This usually implies the use of high-quality digital stirrers. Alternately, with cheaper stirrers, the base plate should be thermally insulated from the vial containing the sample to eliminate variations in sample temperature during extraction. Magnetic stirring is efficient when fast rotational speeds are applied. Figure 9 illustrates the dependence of the equilibration

</table>

Flow-through techniques are very useful in continuous monitoring applications and can also be automated. However, some additional flow-metering devices may be required to ensure reproducible mass-transfer conditions. The most efficient agitation method evaluated to date for SPME applications is the direct probe sonication, which can provide very short extraction times, frequently approaching the theoretical limits calculated for perfectly agitated samples. However, this technique has substantial drawbacks associated with large amounts of energy introduced into the system, which cause the sample to heat up and in some cases can lead to decomposition of the analyte. Most of these disadvantages are eliminated when sonication is applied in the flow-through mode.

3.5 Selection of Separation and/or Detection Technique

So far, most SPME applications have been developed for GC, but other separation techniques, including HPLC, capillary electrophoresis (CE) and supercritical fluid chromatography (SFC), can also be used in conjunction with this technique. The complexity of the extraction mixture determines the proper quantitation device. Regular chromatographic and CE detectors can normally be used for all but the most complex samples, for which mass spectrometry (MS) should be applied. As selective coatings become available, the direct coupling to tandem mass spectrometry (MS/MS) and inductively coupled plasma mass spectrometry (ICPMS) becomes practical.

3.6 Optimization of Desorption Conditions

Standard GC injectors, such as popular split-splitless types, are equipped with large volume inserts to accommodate the vapors of the solvent introduced during liquid injections. As a result, the linear flow rates of the carrier gas in those injectors are very low in splitless mode, and the transfer of the volatilized analytes onto the front of the GC column is very slow. No solvent is introduced
during SPME injection, therefore the large insert volume is unnecessary. Opening the split line during SPME injection is not practical, since it results in reduced sensitivity. Efficient desorption and rapid transfer of the analytes from the injector to the column require high linear flow rates of the carrier gas around the coating. This can be accomplished by reducing the internal diameter of the injector insert, matching it as closely as possible to the outside diameter of the coated fiber. Narrow-bore inserts for SPME are commercially available from Supelco for a range of GC instruments.

Other GC injectors, including programmed temperature vaporization (PTV) and septum-equipped programmable injector (SPI) (Varian), can be used with good results for SPME analysis. The use of on-column injectors is limited to those equipped with independent heating and capable of accommodating large diameter columns. Table 3 summarizes the characteristics of GC injectors suitable for SPME analysis.

Desorption time is determined by the temperature of the injector and the linear flow rate of the carrier gas around the fiber. Theoretical desorption times are very short since the diffusion coefficients of analytes in the coating increase and the gas/coating distribution constants rapidly decrease with temperature increase. Table 4 illustrates the decrease in the gas/coating distribution constant for three analytes when the temperature is increased from ambient to 250 °C, which is a typical injector temperature.

In practice, desorption temperature is determined by the thermal stability of the coating. It is advisable to use high desorption temperatures in order to achieve fast desorption. However, application of excessive temperatures adversely affects the coating’s longevity and results in bleeding of the polymer, rendering the separation and quantitation difficult.

To achieve good separation efficiency, it is crucial that the injection band width is as small as possible. The few seconds needed to transfer the analytes onto the front of the column when narrow-bore inserts are used might be still too long to produce narrow bands for very volatile analytes. It is necessary, therefore, to refocus the band after the desorption is finished. A thick film column or cryofocusing can be used for this purpose. It is always advisable to consider the application of a short length of deactivated narrow-bore fused-silica tubing as a retention gap. This will eliminate the broadening effect created by the temperature gradient existing in the column close to the injector. Except for the most volatile analytes (gases), the combination of a thick film column and the retention gap is usually sufficient to refocus the injection band, and cryofocusing does not have to be applied.

Parameters which control the desorption process in the HPLC interface are analogous to those in GC applications. In addition to temperature and flow rate, the composition of the mobile phase also affects the process. In many cases, it is possible to use the mobile phase without any modifications, as in the analysis of polynuclear aromatic hydrocarbons (PAHs). In some instances, addition of an appropriate solvent to the interface will assist desorption. The linear flow rate of the mobile phase should be maximized by choosing a small internal diameter tubing for the desorption chamber. Temperature also plays an important role in accelerating the desorption process as illustrated in Table 5. At ambient desorption temperatures, a significant carryover of Triton X-100 was observed, which was corrected when the temperature was raised to 135 °C.

Table 5 Effect of desorption chamber temperature on carryover of Triton X-100 using Carbowax™/DVB fiber
3.7 Optimization of Sample Volume

The volume of the sample should be based on the estimated distribution constant \( K_{fs} \). The distribution constant can be estimated by using literature values for the target analyte or a related compound with the coating selected. For the PDMS coating, it can also be directly calculated. For example, for a 5% error, it can be estimated by Equation (11):

\[
n = \frac{K_{fs}V_f}{V_s + K_{fs}V_f} \tag{11}
\]

As the sample volume \( V_s \) increases, so does the amount of analyte extracted until the volume of the sample becomes significantly larger than the product of the distribution constant and volume of the coating (fiber capacity \( K_{fs} \ll V_s \)). At this point, the sensitivity of the method does not increase with further increase in volume. In practice, the limiting volume can be calculated from the dependence in Equation (12):

\[
V_s = \frac{100K_{fs}V_f}{E} \tag{12}
\]

where \( E \) is the magnitude of the relative measurement error (%). For example, for a 5% error, it can be estimated that \( V_s = 20K_{fs}V_f \). This means that for \( K_{fs} \) values of up to about 200 and a 100 µm coating, a 2 mL vial is sufficient to give maximum sensitivity, while a 40 mL vial can be used for \( K_{fs} \) values smaller than 4000, etc. Using sample volumes larger than the limiting value does not only maximize the sensitivity, but also results in better precision since variations of the sample volume do not affect the results. Figure 10 illustrates this relationship graphically. The \( n_I \) corresponds to the amount of analyte extracted from an infinite sample volume. Even for a moderate distribution constant of 1000, characteristic for many volatiles, for the 100 µm PDMS coating (see Figure 10a) there is a substantial difference in the amount extracted when varying the sample volume within a few milliliters range. Increasing the volume from 1 mL to 10 mL results in sensitivity improvement by over 50%. The change is more dramatic for semivolatile analytes. The variation is less significant for thinner coatings (Figure 10b and c), but the sample volume should still be considered when analytes characterized by large distribution constants, such as PAHs, are analyzed. In practice, the sample size is determined by the available vials. The discussion above should assist in the choice of the most appropriate vial size.

In headspace SPME, the analytes partition to the gaseous phase as well as to the coating. Very volatile compounds preferentially accumulate in the headspace resulting in a very substantial loss in sensitivity when the headspace volume is large. Figure 11 presents the dependence of the amount of analyte extracted by a 100 µm fiber on the headspace-to-sample volume ratio for three vial sizes: 4, 15 and 40 mL. The following values of distribution constants have been used: \( K_{fs} = 400, 2500 \) and \( 1000 \), and \( K_{hs} = 0.15, 0.7 \) and 1.24, corresponding to chloroform, 1,1,1-trichloroethane and carbon tetrachloride, respectively. In Figure 11, \( n_I \) is the amount of analyte extracted from an infinite sample volume. The \( n/n_I \) ratio is always the largest for chloroform, which has the lowest \( K_{hs} \) value, even though its \( K_{fs} \) value is also the lowest. This is because only a small fraction of the analyte is present in the sample
heads or therefore the equilibrium concentration of the analyte in the sample remains relatively high. For the two other curves and low headspace volumes, \( n/n_I \) is higher for carbon tetrachloride than for 1,1,1-trichloroethane, which is consistent with the values of their distribution constants \( K_{fs} \). However, as carbon tetrachloride has the largest \( K_{hs} \), \( n/n_I \) drops faster for this compound than for 1,1,1-trichloroethane, as a result of which the respective two lines cross each other. The biggest relative increase in \( n/n_I \) when moving from small to large vials (≈44%) is observed for 1,1,1-trichloroethane, characterized by the highest \( K_{fs} \) value. For compounds with lower \( K_{fs} \) values the relative increase in the amount extracted is much lower (≈16 and ≈12% for chloroform and carbon tetrachloride, respectively). It is therefore the combination of \( K_{fs} \) and \( K_{hs} \) for a given compound that determines the magnitude of the effect of sample volume on the amount of analyte extracted by the fiber in three-phase systems involving headspace.\(^{(23)}\)

Headspace volume can have a significant effect on equilibration times (extraction kinetics). If the amount of the analyte extracted by the fiber at equilibrium is negligibly small compared to the amount present in the headspace equilibrated with the sample prior to the extraction, the analyte is extracted almost exclusively from the gaseous phase, and the process is much faster compared to the case when significant amounts of the analyte have to transported from the liquid sample to the fiber via the headspace. Assuming that this situation occurs when 95% of the analyte is extracted exclusively from the headspace, the criterion that must be fulfilled can be described by Equation (13). The assumption is reasonable, as a 5% difference usually falls within the limits of experimental error for trace SPME/GC analysis:

\[
\frac{K_{hs}V_f}{K_{hs}V_h} < 0.05
\]  

(13)

The above criterion means that the capacity of the headspace (\( K_{hs}V_h \)) needs to be at least 20 times larger than the capacity of the fiber (\( K_{fs}V_f \)) to achieve rapid extraction. For a given sample volume \( V_s \), this can be achieved by using a large enough headspace volume, or by increasing \( K_{hs} \). The latter can be accomplished by increasing the temperature or by salting the analyte out of the liquid phase. When the criterion of Equation (13) is fulfilled, equilibration can take as little as a few minutes, and is almost independent of the agitation conditions (provided the analyte is equilibrated between the liquid phase and its headspace before the extraction begins). It should be emphasized, however, that the increase in headspace capacity causes a significant loss in sensitivity. In any case, it should be remembered that changing the vial size during the optimization process can affect not only the sensitivity, but also the equilibration time if the headspace/sample volume ratio is different in the new vial.

### 3.8 Determination of the Extraction Time Profile in a Pure Matrix

Extraction time profiles for the analyte should be determined first in a pure matrix, such as dry air, pure water or sand, to obtain basic understanding of the kinetics of analyte transfer from the matrix to the fiber under given mass-transfer conditions. The profile is determined by extracting samples of identical composition for progressively longer periods of time and plotting the resultant area counts vs. time. The mass of the analyte extracted can be quantified by a proper calibration procedure, e.g. syringe injection of a standard solution of the analyte in an appropriate solvent. In GC, this type of calibration is reliable only when non-vaporizing injectors are used (PTV, SPI, heated on-column).
3.9 Determination of the Extraction Time

An optimal approach to SPME analysis is to allow the analyte to reach equilibrium between the sample and the fiber coating. The equilibration time is defined as the time after which the amount of analyte extracted remains constant and corresponds within the limits of experimental error to the amount extracted after infinite time. Care should be taken when determining the equilibration times, since in some cases a substantial reduction of the slope of the curve might be wrongly taken as the point at which equilibrium is reached. Such a phenomenon often occurs in headspace SPME determinations of aqueous samples, where a rapid rise of the equilibration curve corresponding to extraction from the gaseous phase only is followed by a very slow increase related to analyte transfer from water through the headspace to the fiber. Figure 12 illustrates an example of such a curve for phenanthrene. The amount extracted increases rapidly in the first five minutes, but the equilibrium is not reached until much later. Determination of the amount extracted at equilibrium allows the calculation of the distribution constants.

When equilibration times are excessively long, shorter extraction times can be used. However, in such cases the extraction time has to be strictly controlled to assure good precision. Figure 13 presents equilibration time profiles for \( p,p'-1,1,1\)-trichloro-2,2-bis\((p\)-chlorophenyl\)ethane (DDT) (a) and Dichlorvos (b). The equilibration time for DDT is about two hours. At equilibrium, small variations in the extraction time do not affect the amount of the analyte extracted by the fiber. On the other hand, at the steep part of the curve, even small variations in the extraction time may result in significant variations of the amount extracted. The relative error is the larger, the shorter is the extraction time. For a 10 min extraction (Figure 13a), the relative error caused by varying the extraction time by ±1 min is as high as 20%. It drops to 5% after 50 min extraction since more analyte accumulates onto the fiber. The timing is even more critical for short exposure times when the equilibration curve rises rapidly. Figure 13(b) shows an example when a 1 min deviation from 10 min sampling time results in 50% relative error of determination.

Autosamplers can measure the time very precisely and the precision of analyte determination can be very good, even when equilibrium is not reached in the system. However, this requires the mass-transfer conditions and the temperature to remain constant during all experiments.

3.10 Calculation of the Distribution Constant

The distribution constant of the target analyte defines the sensitivity of the method. It is not necessary to calculate the fiber coating/sample matrix distribution constant, \( K_{fs} \), when the calibration is based on isotopically labeled standards or standard addition, or when identical matrix and headspace volumes are used for the standard and for the sample with external calibration. However, it is always advisable to determine \( K_{fs} \) since this value gives more
Table 6 Ranges of $K$ values obtained when the amount of the analyte extracted by the fiber, $n$, determined experimentally falls within ±5% (relative) of the true value, for two different fiber coating thickness and two sample volumes

It is important to consider the sample volume when calculating the value of $K_{fs}$. Table 6 presents the ranges of $K$ values that are obtained when the amount of the analyte extracted by the fiber, $n$, determined experimentally falls within ±5% (relative) of the true value, for two sample volumes (2 and 35 mL) and two fiber coating thicknesses (100 and 7 µm). A ±5% error can be assumed typical for trace analysis by SPME/GC. To correctly estimate the distribution constant for the direct extraction mode can be calculated from the following dependence (Equation 14) obtained from Equation (11):

$$K_{fh} = \frac{nV_s}{V_f(C_0V_s - n)}$$

(14)

However, extreme caution is advised when using this equation, since it assumes that after the extraction, the analyte concentration in the sample does not change significantly. If this equation is used by mistake when the $K_{fs}$ value is large or the sample volume is too small, the result of the calculation does not correspond to $K_{fs}$, but rather to the sample/coating phase volume ratio ($V_s/V_f$).

To determine the coating/matrix distribution constant when headspace is present in the vial, knowledge of the matrix/headsace distribution constant is required (Equation 16):

$$K_{fs} = \frac{n(K_{hs}V_h + V_s)}{V_f(C_0V_s - n)}$$

(16)

If the distribution constant is low and the total volume of the sample is high, a good estimate of $K_{fs}$ can be obtained from the relationship, Equation (15):

$$K_{fs} = \frac{n}{C_0V_f}$$

(15)

For analytes with an unknown Henry’s constant, Equation (18) can be used:

$$K_{fs} = \frac{nK_{fh}V_s}{K_{fh}V_fC_0 - nK_{fh}V_f - nV_h}$$

(18)
Equation (18) is obtained by substituting $K_{hs} = K_f/K_{fh}$ into Equation (16) and rearranging it. The fiber/gas distribution constant can be found by extracting target compounds from air mixtures by using a simple bulb experiment.\(^{(21)}\) In addition, $K_f$ can be obtained directly from a chromatographic run when the stationary phase is made of the same material as the fiber coating. For compounds which have low vapor pressures, the amount of analyte present in the headspace is very small, especially if the volume of the headspace is kept to a minimum. Therefore, in this situation, the headspace volume can be neglected altogether and Equation (14), which corresponds to direct extraction, can be applied.

### 3.11 Optimization of Extraction Conditions

Extraction temperature increase causes an increase in the extraction rate, but simultaneously a decrease in the distribution constant. In general, if the extraction rate is of major concern, the highest temperature which still provides satisfactory sensitivity should be used. Figure 14 demonstrates the effect of temperature on extraction of methamphetamine from water. At room temperature equilibration takes several hours. When the temperature is raised to $60^\circ C$, the equilibration time is less than 20 min for both compounds. When the temperature is further increased to $73^\circ C$, the equilibration time is reduced to a few minutes (Figure 14a). Very short equilibration times indicate that the majority of the analytes extracted by the fiber originate from the headspace. This conclusion is further supported by the stirring data obtained for $60^\circ C$ (Figure 14b). At this temperature, the amount of analytes extracted is almost independent of the agitation conditions. The amount extracted is lower by over an order of magnitude compared to room temperature, but still provides sufficient sensitivity to quantify these drugs at the parts per billion level, which is adequate for screening applications.

Adjustment of the pH of the sample can improve the sensitivity of the method for basic and acidic analytes. This is related to the fact that unless special coatings are used, SPME can extract only neutral (nonionic) species from water. By properly adjusting the pH, weak acids and bases can be converted to their neutral forms, in which they can be extracted by the SPME fiber. To make sure that at least 99% of the acidic compound is in the neutral form, the pH should be at least two units lower than the $pK_a$ of the analyte. For the basic analytes, the pH must be larger than $pK_b$ by two units. Figure 15 illustrates the increase in the amount of amphetamine and methamphetamine extracted as the pH is increased.\(^{(22)}\) In practice, it may be difficult to use pH adjustment with direct extraction, since the coating might be damaged by solutions of very high or very low pH values. Headspace SPME is therefore a natural choice for pH-adjusted matrices. The sample should be buffered to ensure good reproducibility when basic or acidic compounds are present in it.

Addition of any ionic salt to aqueous samples generally increases the fiber/matrix distribution constants of neutral organic molecules. However, when the analytes are in the dissociated form, a decrease in the amount extracted is observed. This is related to the fact that the activity coefficients of ionic species in water decrease with the increase in the ionic strength of the solution. It is important, therefore, to first convert the analytes to neutral

---

forms. Figure 16 illustrates the increase in the amount of amphetamines extracted from a solution when any ionic salt is added after the pH is lowered by KOH addition.

3.12 Determination of the Linear Dynamic Range of the Method for a Pure Matrix at Optimum Extraction Conditions

Modification of the extraction conditions affects both the sensitivity and the equilibration time. It is advisable, therefore, to check the previously determined extraction time before proceeding to the determination of the linear dynamic range. This step is required if substantial changes of the sensitivity occur during the optimization process.

SPME coatings include polymeric liquids such as PDMS, which by definition have a very broad linear range. For solid sorbents, such as Carbowax™/DVB or PDMS/DVB, the linear range is narrower because of a limited number of sorption sites on the surface, but it still can span over several orders of magnitude for typical analytes in pure matrices. In some rare cases when the analyte has extremely high affinity towards the surface (e.g. basic proteins adsorption on poly(acrylic acid) or bioaffinity coatings), saturation can occur at low analyte concentrations. In such cases, the linear range can be expanded by shortening the extraction time. In the majority of practical applications developed to date, it is the dynamic range of the detector that limits the linear response of SPME methods.

3.13 Selection of the Calibration Method

Standard calibration procedures can be used with SPME. The fiber blank should be first checked to ensure that neither the fiber nor the instrument cause interferences with the determination. The fiber should be conditioned prior to the first use by desorption in a GC injector or a specially designed conditioning device. This process ensures that the fiber coating itself does not introduce interferences. Fiber conditioning may have to be repeated after analysis of samples containing significant amounts of high-molecular-weight compounds, since such compounds may require longer desorption times than the analytes of interest.

When the matrix is simple (e.g. air or groundwater), the distribution constants are very similar to those for pure matrix. It has been shown, for example, that typical moisture levels in ambient air, as well as the presence of salt and/or alcohol in water in concentrations lower than 1%, usually do not change the K values beyond the 5% RSD typical for SPME determinations. In many such instances, calibration might not be necessary since the appropriate distribution constants which define the external calibration curve are available in the literature or can be calculated from chromatographic retention parameters. External calibration can also be used successfully when the matrix is more complex, but well defined (e.g. process streams of relatively constant composition). Of course, calibration standards have to be prepared in such cases in the matrix of the same composition rather than in the pure medium (e.g. water).

A special calibration procedure, such as isotopic dilution or standard addition, should be used for more complex samples. In these methods, it is assumed that the target analytes behave similarly to spikes during the extraction. This is usually a valid assumption when analyzing homogeneous samples. However, it might not be true when heterogeneous samples are analyzed, unless the native analytes are completely released from the matrix under the conditions applied. Moreover, whenever any of these methods is used, an inherent assumption is made that the response is linear in the concentration range between the original analyte concentration and the spiked concentration. While this is usually true for fibers extracting the analytes by absorption (PDMS, PA) and detectors with wide linear range, for example, a flame ionization detector (FID), problems may arise when porous polymer fibers (PDMS/DVB, Carbowax™/DVB) are used, or when the detector applied has a narrow linear dynamic range. It is important, therefore, to check the linearity of the response using standard solutions before applying standard addition or isotopic dilution for calibration. To improve the accuracy and precision, multipoint standard addition should be used whenever practical.

3.14 Optimization of Extraction Conditions for Heterogeneous Samples

Optimizing the process that releases native analytes from the matrix components (e.g. solid particles) is more
difficult since the analyte/matrix association is usually poorly understood. Whenever a new type of complex matrix is considered, a study must be conducted to find the optimum extraction conditions which give the fastest and most complete release and extraction of native analytes. Typically, an empirical approach is taken and several parameters are varied, such as temperature and type of additives. Change of extracting phase type, used in optimization of many solvent extraction methods, is of limited value in SPME since the fiber coating does not interact directly with solids present in the matrix. Heating can release analytes from a solid matrix, but sometimes heating is not adequate because analytes are bound too strongly or the matrix or analytes are unstable at higher temperatures. Additives (matrix modifiers) which enhance the extraction of analytes are an alternative to heating. The additive selected should enhance the release of analytes from the matrix but not interfere with the partitioning of analytes into the fiber coating or with the analysis of the extracted compounds. Successful modifiers for SPME include nonvolatile acids, salts and water.\(^{(2,24)}\) Better understanding of the analyte–matrix interaction would allow a more rational choice of appropriate additives. In-depth investigation of sample matrices should be considered.

Frequently, the conditions optimal for releasing the analytes from the matrix are different from the conditions that are optimal for partitioning them into the coating. In most cases, high temperature is used to remove native analytes from the matrix. Higher temperatures, however, reduce the distribution constant and thus the sensitivity of the method. To eliminate this disadvantage, a cooled-fiber approach can be applied to condense analytes onto the fiber.\(^{(2)}\)

Optimization of extraction parameters is considered complete when the recoveries of analytes present in native samples match those for spikes. This verification is performed based on extraction results obtained for certified standard reference materials (SRMs), or by a comparison with standard extraction methods. Once the method is verified, quantitation is performed by comparing extracted amounts of native and spiked analytes. Table 7 illustrates the comparison of results of PAH analysis by SPME with certified reference values obtained for urban air particulate (NIST 1649).\(^{(25)}\) The method consists of static hot water extraction at 250 °C, followed by a cool-down period to increase the amount of analytes absorbed by the PDMS coating.

### 3.15 Verification of the Equilibration Time, Sensitivity and Linear Dynamic Range for Real Sample Matrices

The sample matrix can affect not only the distribution constant, but also the equilibration time. When the matrix is heterogeneous (e.g. an aqueous sample with solid particulate matter), the kinetics of analyte release might determine the overall extraction rate. To operate at optimum sensitivity, extraction time needs to be adjusted accordingly.

The amount of analyte extracted by the fiber changes substantially when the coating is swollen owing to absorption of a large amount of an interfering major matrix component. To produce swelling, the amount of interference which needs to be absorbed must be substantial compared to the mass of the coating (more than 1%), which translates to about 10 µg for a 100-µm PDMS fiber. In trace analysis of homogeneous aqueous samples this would rarely be the case, since it requires that the interfering compound has good solubility in both the aqueous matrix and the coating. However, the phenomenon might occur if the interference exists as a separate phase, such as an oily suspension or dispersed hydrophobic humic material.\(^{(26)}\) In such cases, SPME is of limited value as a quantitation tool, since both the distribution constant and the volume of the coating can change during extraction. The effect of high-molecular-weight compounds on the results of SPME analysis of aqueous samples can be eliminated by using microporous hollow fiber membranes to isolate the coating from direct contact with the sample.

Apart from the extraction time, the linear dynamic range and method sensitivity should also be examined for real matrices. Typically, no differences between model solutions and real samples occur when fibers extracting the analytes by absorption (PDMS, PA) are used. However, when porous polymer fibers are used, competitive adsorption of interfering matrix components with large distribution ratios can reduce the uptake of analytes of interest and cause nonlinearity of the calibration curves. The adverse effect of competitive sorption can be minimized by extracting the analytes under nonequilibrium conditions. For example, short extraction can be performed with a well-agitated sample, or static extraction can be used. In both cases, the uptake of volatile analytes with lower distribution ratios is only

</table>
slightly affected, while that of less volatile compounds with large distribution ratios is significantly reduced.

The sample matrix can affect not only the extraction process, but also the separation. It should be verified that no matrix components co-elute with the analytes of interest, interfering with proper quantitation.

3.16 Determination of Method Precision

The most important factors affecting precision in SPME are listed below:

- agitation conditions
- sampling time (if nonequilibrium conditions are used)
- temperature
- sample volume
- headspace volume
- vial shape
- condition of the fiber coating (cracks, adsorption of high-molecular-weight species)
- geometry of the fiber (thickness and length of the coating)
- sample matrix components (salt, organic material, humidity, etc.)
- time between extraction and analysis
- analyte losses (adsorption on the walls, permeation through Teflon®, absorption by septa)
- geometry of the injector
- fiber positioning during injection
- condition of the injector (pieces of septa)
- stability of the detector response
- moisture in the needle

The majority of these factors and their effect on method precision have already been discussed. A brief explanation of the remaining parameters follows.

Reproducibility of the sample and headspace volumes can impact on the precision of SPME methods. The volume of the sample has an impact on the amount extracted when only a few mL sample is used (see the discussion above). Therefore, small samples, such as 1 mL, need to be measured very carefully. For large samples, small variations in the sample volume do not have a substantial effect on precision of the data. Obviously, the volume of all the samples and standards must be the same to obtain valid results.

Headspace volume can be an important factor determining precision of the results in three-phase systems. It is relatively easy to measure sample volume accurately. However, vials are not manufactured to have exactly the same total volume. Wall thicknesses and bottom shapes may differ from vial to vial. Also, the shape of the septum in a closed vial can vary from concave to convex. All these factors will affect the total volume of the system, and therefore the headspace volume, which is the difference between the total volume and the sample volume. Such differences (especially related to septum shape) are usually more pronounced in small vials, therefore worse precision can usually be expected when they are used. In addition to keeping the sample and standard volumes constant throughout all the experiments, vials of the same volume should be used for all samples and standards, so that the headspace volume is constant from vial to vial. This becomes a bigger challenge for small vials, when a small absolute variation in headspace volume could translate to a large relative difference.

The condition of the fiber is very important. The presence of high-molecular-weight species, such as proteins and humic matter, adsorbed on the surface of the fiber, causes a change in sorption characteristics. In some cases, the substances adsorbed can be removed by washing the fiber in appropriate solvents. When the coating is badly cracked, a small amount of the matrix itself kept in the cracks by capillary forces might be transferred into the analytical instrument and adversely affect its operation.

The volume of the coating determines the amount of analytes extracted. Fibers which begin to lose the coating phase should be replaced immediately. The length of the fiber should be monitored to ensure equivalency when changing the fiber. If the length of the fiber (thus the volume of the coating) is different, an appropriate correction factor should be incorporated.

Time between preparation of standards or sample collection and extraction should be minimized. After placing aqueous samples or standards in a vial, analytes begin to interact with the walls of the container. Very hydrophobic substances are frequently strongly adsorbed on the surfaces and are not available for extraction by the coating. This results in lower than expected extracted amounts. One way to prevent this problem is to use vials with more inert walls, for example silanized glass or Teflon®. For volatile analytes, it is crucial that new Teflon®-lined septa are always used. Once the Teflon® lining is pierced, the analytes can come into direct contact with the septum material (typically PDMS), which usually results in losses through absorption. Finally, it should be remembered that many volatile compounds can permeate through Teflon® at a relatively high rate. This phenomenon can also contribute to analyte losses when the samples or standards are stored for prolonged periods of time.

Time between extraction and analysis should also be minimized. When this time is longer that a few seconds, the needle of the fiber assembly should be sealed with a septum and preferentially cooled down to reduce losses and interferences. After the fiber is withdrawn from the sample, it begins to equilibrate with ambient air. This process is slow when the fiber is withdrawn into the...
needle. Therefore, the few seconds which are normally required to transfer the fiber to the injection port of a GC do not result in any substantial losses of the analytes. However, when the fiber is to be stored for some time before the analysis, sealing of the needle is necessary. In addition, this protection prevents contamination of the fiber with interferences or even target analytes which might be present in ambient air. Cooling of the SPME device might be necessary to extend the stability of the volatile analytes in the coating.\(^{(11)}\)

### 3.17 Determination of the Method Detection Limit

Several methods are described in the literature to determine the method DL. The most widely accepted definition is based on estimating the DL using low concentration spikes and calculating the standard deviation of the determination. The DL is then defined as 3 times the standard deviation obtained for the measurement value not higher than 10 times the method DL.

### 3.18 Validation of the Method

Validation of the method might include comparison of quantitation results with certified values obtained for SRMs which have similar matrix and target analytes. Another approach is to validate the method against officially accepted techniques for the analysis of target analytes. Table 8 summarizes the results of multilevel validation of SPME against the standard purge and trap technique for the analysis of BTEX (benzene, toluene, ethylbenzene, \(m\)-xylene, \(o\)-xylene, \(p\)-xylene) compounds in water. The regression line has a slope close to one, with a very small intercept value and linear correlation coefficients better than 0.99 for all species. The very good agreement between both methods indicates suitability of headspace SPME for the analysis of volatile organic compounds (VOCs) in aqueous samples.\(^{(27)}\)

Finally, interlaboratory studies are frequently performed to validate a method. Table 9 summarizes the results obtained in a round robin test on pesticide analysis by SPME, which involved several laboratories in Europe and North America.\(^{(28)}\) In general, the results are characterized by good repeatability, which proves that SPME is a valid method for the determination of pesticides at trace levels. As expected, the interlaboratory and reproducibility standard deviations are higher since they include differences between laboratories. However, they are still satisfactory. The results indicate also that SPME is an accurate method. In all cases, the confidence intervals of the gross average and the true value overlap, which indicates that any differences between the two respective values are due to random factors. Interestingly, for 10 out of 12 compounds, the values of the gross average are slightly lower than the true values. This might be due in part to losses of analytes through adsorption (as described above) in cases where the fiber is to be stored for some time before the analysis, sealing of the needle is necessary. In addition, this protection prevents contamination of the fiber with interferences or even target analytes which might be present in ambient air. Cooling of the SPME device might be necessary to extend the stability of the volatile analytes in the coating.\(^{(11)}\)

All values expressed in \(\mu g L^{-1}\): \(s_t\) – repeatability standard deviation, \(s_L\) – interlaboratory standard deviation, \(s_R\) – reproducibility standard deviation, \(r\) – repeatability, \(R\) – reproducibility, G.A. – gross average, C.I. – confidence interval of the gross average, T.V. – confidence interval of the “true” value.
where the aqueous pesticide solutions were not prepared directly before the analysis, as required by the test protocol.

3.19 Automation of the Method

SPME is a very powerful investigative tool, but it can also be a technique of choice in many applications for processing a large number of samples. To accomplish this task would require automation of the methods developed. As automated SPME devices with more advanced features and capabilities become available, automation of the methods developed becomes easier. A currently available SPME autosampler from Varian enables direct sampling with agitation of the sample by fiber vibration, and static headspace sampling. In some cases, custom modifications to the commercially available systems can facilitate operation of the method closer to optimum conditions.

4 APPLICATIONS OF SOLID-PHASE MICROEXTRACTION

Most of the methods developed so far are applicable for clean matrix samples and only a few optimization parameters have been fully investigated. Many other potential applications are still waiting to be explored. The results obtained are very promising. A basic understanding is emerging of the basic matrix types: gaseous, liquid and solid and is summarized below. General approaches to facilitate successful extraction of these systems are emphasized. The object of this section is not to demonstrate a comprehensive review, but to give examples of successful SPME applications.

4.1 Gaseous Matrices

All SPME methods developed to date for gas analysis are directed towards air analysis. However, the approaches described are also suitable for the analysis of other gas mixtures.

Model studies on extraction from air have been performed by two methods: static and (the more realistic) dynamic. In the static method, the target compounds are introduced to a glass bulb equipped with a septum. After the analytes vaporize completely, the SPME fiber is introduced to the bulb through a septum. In practical ambient air measurements, the system is not static, since convection is always present. It is more appropriate, therefore, to use dynamic gas chambers for the modeling studies.\(^{1,8}\) Equilibration times for extraction of trace contaminants from moving air are short, as predicted from the theory. Figure 17 shows the equilibration time profiles obtained for a 20 L chamber operated at 200 mL min\(^{-1}\). The equilibration times are between 30 and 100 s, corresponding to pentane and undecane, respectively. They are close to theoretical values for perfect agitation.

![Figure 17](image.png)

**Figure 17** Representative extraction time profiles obtained for a standard gas mixture containing (a) benzene, (b) toluene, (c) ethylbenzene, (d) \(p\)-xylene, (e) \(o\)-xylene, (f) \(\alpha\)-pinene and (g) 1,3,5-trimethylbenzene. PDMS-coated fiber.
conditions. Increased air flow decreases the equilibration times for less volatile analytes.

PDMS coating is generally not affected by major air components. A small decrease in the response for organics was observed only for samples of relative humidity close to 100%. The primary experimental parameter which controls the response is temperature. However, the effect of temperature on the distribution constant can be easily predicted (Equation 19), since log \( K_{fg} \) is linearly related to \( 1/T \) and the heat of vaporization of the pure solute, \( \Delta H^V \):

\[
\log_{10} K_{fg} = \frac{\Delta H^V}{2.303RT} + \left( \log_{10} \frac{RT}{T_0 p^*} - \frac{\Delta H^V}{2.303RT^*} \right)
\]  (19)

where \( p^* \) is the analyte vapor pressure at a known temperature \( T^* \) for a pure solute, and \( \gamma_i \) is the activity coefficient of the solute in the coating. In other words, \( K_{fg} \) can be calculated for given extraction conditions using the temperature measured and the heat of vaporization for the target compound. Figure 18 illustrates the above relationship graphically for a range of compounds varying in volatility. The linear relationship is clearly illustrated.

In addition, as has been described in section 2, the heat of vaporization and activity coefficient are related to the retention time of a compound on the GC column using the same coating material as the SPME fiber. Thus, the appropriate distribution constants can be determined directly from the retention indices of the target analytes. For PDMS coating, the following relationship between the gas/coating distribution constant and the LTPRI has been found (Equation 20):

\[
\log_{10} K_{fg} = 0.00415 \times \text{LTPRI} - 0.188
\]  (20)

The differences between the values of distribution constants calculated from the retention indices and determined directly were generally found to be insignificant. This approach can be extended to other coatings as long as columns with appropriate coatings are available. In addition, using this approach it is possible to determine the distribution constants of unidentified compounds, therefore it is possible to use SPME for the determination of parameters like total petroleum hydrocarbons (TPH) in air. A comparison of SPME/PDMS with the standard charcoal tube technique obtained for an air sample drawn near a gas station, resulted in 262 and 247 µg L\(^{-1}\), correspondingly.\(^{(5)}\) The values show a very good agreement indicating that the approach described above can be used to quantify analytes in gaseous samples without the need for identification. It should be pointed out, however, that this approach can be used only with detectors whose response is more or less independent of the nature of the analyte (e.g. FID for the analysis of hydrocarbons).

SPME has superior sensitivity for short term monitoring compared to traditional devices, which are limited by the gas throughput. The SPME fibers can also be used at high temperatures. For example, Figure 19 illustrates the identification of several polycyclic aromatic hydrocarbons (PAHs) directly in diesel exhaust. A typical distribution of these pollutants is illustrated. The advantages of SPME...
for long-term sampling are not as clear at the present time. Typically, the fiber reaches equilibrium with the air components in the first few minutes and then does not accumulate any more analytes, independently of the exposure time. However, the sensitivity of the SPME technique can be improved by using thicker, more selective coatings or by cooling the fiber to increase the PDMS/gas distribution constant. Another approach is to incorporate the derivatization reagent in the coating to allow “trapping” of the analyte in the coating. All these modifications enhance the sensitivity of SPME in air monitoring.

SPME can also be used as an integrated sampling device. Theoretical principles of this approach have been described in section 2. The simplest way to accomplish this task is to retract the fiber into the needle. An alternative approach is to use a chemical reaction in the coating. Figure 20 shows the extraction of low-molecular-weight carboxylic acids from a small volume of air using a fiber doped with PDAM. As expected, a linear dependence between the amount of acid extracted and time is obtained until about 60% of the acid is extracted from the sample. In practice, however, when the fiber is exposed to ambient air, analytes accumulate linearly with concentration for as long as the fiber is exposed or the derivatization reagent is substantially consumed. This approach is particularly useful for integrated sampling of very low analyte concentrations in air. Another interesting application of SPME coupled to an on-fiber derivatization step was demonstrated for analysis of aldehydes in air. In this case o-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine was used as derivatization reagent and the products, oximes were analyzed by GC.

\[ K_{fw} = K_{fg}K_{aw} \]  

where \( K_{fg} \) can be determined from chromatographic data as discussed above, and \( K_{aw} \) is the air/water distribution constant for a given analyte which can be found in the tables of Henry’s constant values. For example, the equation for a PDMS coating and aqueous matrix can be
calculated from Equation (22):

\[ K_{fw} = 0.00415 \times \text{LTPRI} - 0.188 + \log_{10} K_{aw} \]  (22)

This equation is obtained after substitution of the expression for \( K_{fr} \) given by Equation (21) into Equation (20). The \( K_{fw} \) values found using this equation agree very well with experimental data\(^{(3)}\) considering that typically the errors in Henry's constant determination are larger than 10%. In addition, the Henry's constants are similar for closely related compounds, as illustrated in Figure 21. As could be predicted from Equation (22), the slopes of the lines are similar, but their intercepts vary because of the differences between the average values of Henry's constant for the different classes of compounds. This relationship enables quantitation of unknown analytes in water provided that the class to which a compound belongs is known.

Several reports indicated the existence of a linear relationship between the coating/water distribution constant and octanol–water distribution constant, \( K_{ow} \).\(^{(30)}\) Considering the discussion above, such relationships are expected to exist only for individual classes of compounds, such as aromatic hydrocarbons. Because the activity coefficients of various classes of analytes in octanol are expected to be different from those in PDMS or other fiber coatings, the relationship between the two extracting phases will vary with the change of chemical properties of the analytes. It is possible, however, to predict the general trends in \( K_{fw} \) within a group of related compounds by using the corresponding values of \( K_{ow} \).

The above discussion pertains to pure water as the sample matrix. The presence of other components in water might affect the distribution constants of the analytes. Also, liquid chromatographic experience gives some clues about the trends in the distribution constant change with modification of the matrix. For example, addition of any ionic salt would generally result in an increase in the distribution constant for neutral organics, but the change is expected to be noticeable only if the concentration of the salt exceeds 1%. Also, the presence of water-miscible polar organic solvents may change the properties of the matrix by reducing its polarity. In addition, swelling of the polymer with the solvent might occur for polar coatings, resulting in a change of the coating volume and possibly also of \( K_{fr} \). However, the change is not expected to be substantial when the concentration of the solvent is below 1%.\(^{(31)}\) When samples contain higher amounts of salt and/or dissolved organics, but they are well defined so that pure matrix can be prepared, external calibration using standards in the matrix may still be appropriate. Otherwise, standard addition (preferentially of isotopically labeled analytes) should be used to compensate for variations in the matrix composition.

A major analytical challenge is always associated with the analysis of samples containing solids, such as sludge. Several approaches can be implemented with SPME. Sometimes modification of the extraction conditions, such as temperature, pH, salt and other additives, facilitates the displacement of analytes into the aqueous phase or the headspace, resulting in distribution constants similar to those for pure water. In certain cases, direct extraction is not possible because of a very dirty matrix or pH conditions which damage the fiber (above pH 12 for the PDMS coating). In such situations, the headspace mode is more suitable for many applications. Even semivolatiles can be analyzed by this method as long as the extraction temperature is sufficiently high, and good agitation conditions are provided. Application of SPME with membrane protection can assist in the extraction of nonvolatile species in the presence of high-molecular-weight interferences which are able to alter the properties of the coating (e.g. proteins or humic material).\(^{(26)}\)

4.3 Solid Matrices

Accurate quantitation of target analytes in solids represents a very significant challenge to the analytical community. Although SPME cannot be used directly to extract analytes from solids, several approaches can be taken to facilitate simple sample preparation. For volatiles, the typical approach is to perform headspace analysis. To release the analytes from the matrix quantitatively, the temperature needs to be increased. This facilitates extraction and improves the kinetics of the process, but it also decreases the distribution constant. Typically, a maximum is observed for the relationship between the amount of analyte extracted by the fiber and temperature.\(^{(2)}\) Initially, the loss of sensitivity due to decreased distribution ratio is more than compensated.
for by the increased concentration of the analyte in the headspace. At even higher temperatures, the loss of sensitivity becomes predominant and the amount of analyte extracted by the fiber decreases. The inherent loss of sensitivity associated with the decrease of the distribution constant at high temperatures can be compensated for by cooling the fiber. However, this approach has not yet been commercialized. Alternatively, matrix modifier can be added to the solid sample. Water has been found to be very effective in displacing the analytes from the solid surfaces for many types of samples, especially at elevated temperatures.

Another successful approach to SPME analysis of solids involves the use of water or a polar organic solvent, such as methanol, for the extraction of the analytes from the solid matrix prior to SPME analysis. When a polar solvent is used, the extract is spiked into pure water. Low-temperature water extraction followed by SPME was found to be a very useful approach for polar compounds, such as herbicides. Application of methanol with water spiking, on the other hand, has been found to be useful for the analysis of volatile hydrocarbons. An interesting modification to the above procedure involves volatilizing the extract followed by fiber extraction from the gaseous phase. Quantitation of analytes in the gas phase is easier, as discussed above.

For less volatile analytes, the methanol approach described above can give good results. In addition, high-pressure hot water extraction is a very suitable solvent-free alternative. Both static and dynamic hot water extraction have their advantages. The static method is very simple and inexpensive since it does not use high-pressure pumps. The dynamic approach, on the other hand, provides an extract which is much cleaner than the original matrix. However, it might be possible to extract many semivolatile target analytes from very dirty matrices with the high-temperature static system, when using the headspace mode of SPME.

### 4.4 Environmental Applications

Much research has been performed on samples of environmental origin, including air, water and sludge, as well as soil. A majority of applications have been developed for aqueous matrices. The results obtained for priority pollutants in water are very encouraging, indicating that in most cases the performance of SPME can meet United States Environmental Protection Agency (USEPA) method requirements. Table 10 summarizes the limits of detection for SPME of volatiles and semivolatiles, including phenols. In each case, the SPME method can be optimized to meet the requirements of the regulatory agency. The following is a brief discussion of the most important accomplishments obtained for several groups of analytes.

BTEX compounds have been the most investigated group of organic compounds of environmental interest. The sensitivity of the SPME/PDMS method for these compounds is very high, allowing mid to low part per trillion determinations in water. BTEX compounds are volatile, so the headspace SPME mode can be used successfully in many applications. Validation research has been conducted to compare the performance of this method with more established alternatives. Figure 22 illustrates an example of a multilevel validation for toluene. The correlation line, indicates the equivalence between the purge and trap technique and SPME. The validation work has been extended to sludge and soils. Considering the complexity of the matrices, the correlation between the purge and trap and headspace SPME techniques was good. Validation work with other VOCs, such as chlorinated hydrocarbons, produced similar conclusions.

The measure of TPH is frequently used to estimate the contamination level of a sample. For air samples, this value can be calculated directly from chromatographic...
data without the need for identification of all individual components as emphasized in the section devoted to gaseous matrices. TPH can then be reported, together with more specific information related to distribution and type of contaminants present in the sample, without the need for performing calibration. Determination of TPH of water samples is possible if the compounds belonging to different classes are separated and identified by a chromatographic technique combined with a quantitation method such as MS. For solids, this value can be obtained after the analytes are transferred into the gaseous or aqueous phase during the extraction process, as described in the section devoted to solid matrices.

Polar volatile solvents like alcohols, ketones and aldehydes are difficult to quantify at trace levels in aqueous matrices. Extraction with nonpolar solvents leads to poor recoveries. More polar solvents cannot be used since they are miscible with water. SPME with a polar polymeric coating has the potential to provide the necessary alternative. Low parts per billion DLs are possible even with FID when PDMS/DVB coating and 35% salt concentration are used.\(^{(5)}\)

Nonpolar semivolatiles, such as PAHs and PCBs are characterized by very large \(K_f\) values, which results in very high sensitivities of SPME determination, frequently reaching low parts per trillion levels.\(^{(36,37)}\) Figure 23 illustrates major components detected and identified in a pulp and paper-mill discharge by solid-phase microextraction/gas chromatography/ion trap mass spectrometry (SPME/GC/ITMS). The major advantage of SPME compared to alternative techniques is its field portability. Frequently, it is very difficult to collect and preserve a representative sample since nonpolar semivolatiles have a tendency to adsorb on solid surfaces of the sampling vessel or the particulate matter. By sampling directly in the field, these phenomena can be eliminated to a large extent.

Polar semivolatiles in natural matrices represent a very significant analytical challenge. Adjustment of pH and salt addition help to reach the required DLs. For example, the LOD obtained for phenols with direct extraction from an acidified solution with a pH stable PA coating are lower than values specified by USEPA. Derivatization with acetic anhydride allows further improvement in sensitivity and chromatographic performance. The derivatization approach also enhances the extraction performance for carboxylic acids and amines, particularly for lower-molecular-weight species.\(^{(1)}\)

Direct extraction of very polar heteroaromatic compounds frequently present in creosote-contaminated groundwater with a PA coating combined with sensitive ion trap MS detection allows low to sub parts per billion DLs for these very water-soluble compounds.\(^{(38)}\)

Pesticides are an analytically difficult group of compounds because of their wide range of chemical structures and properties. Some of them are classified as nonpolar (organochlorine pesticides) and others as very polar semivolatiles (herbicides). Despite this diversity, SPME has been very successfully applied for their determination in aqueous matrices by several research groups.\(^{(39–43)}\) Table 11 summarizes the SPME DLs obtained for several groups of pesticides. They are lower compared to USEPA method LODs. It is even possible to develop single extraction conditions for rapid screening of 60 target pesticides combining three classes: organochlorine, organophosphorus and organonitrogen.\(^{(46)}\)

Application of sodium tetraethylborate as an in situ derivatization reagent enables SPME analysis of some metal ions and organometallic species in aqueous samples. This approach was first used for the determination of methylmercury in water and biota,\(^{(44)}\) followed by the analysis of lead ion and organolead compounds.\(^{(45)}\) In this method, the analytes are first derivatized to their fully ethylated forms before they are extracted by the PDMS fiber. The derivatization products are volatile, therefore the headspace extraction mode of SPME can be applied, facilitating rapid analysis of very complex matrices. The reaction time (about 15 min) typically determines the extraction time. Stirring must be very efficient during derivatization, since the reagent decomposes rapidly after adjustment of the pH. The affinity of neutral forms of organometallic compounds towards PDMS coating is very high, resulting in very low DLs, approaching sub parts per trillion levels for the determination of tetraethyllead in water by SPME/GC/ITMS. This method can be applied to partial speciation of various forms of these metals present in a sample, first by extracting native neutral organometallic species followed by the determination of the ionic forms (after derivatization).

\(^a\) Analyzed with 30% w/w salt added; NA – not available.
\(^b\) Analyzed by SPME with 85 µm PA (poly(acrylate)) fiber.

Application of HPLC to separation of species extracted by SPME opens new possibilities in the determination of nonvolatile and thermally unstable environmental pollutants. Analysis of several alkylphenol ethoxylate nonionic surfactants in water by SPME combined with HPLC has been demonstrated.\(^{46}\) The DLs obtained were at low parts per billion level for individual ethoxamers with ultraviolet (UV) detection, which indicates that trace level determination in natural matrices should be possible by this method.

4.5 Food and Pharmaceuticals

A unique feature of SPME in the analysis of food and drugs is its ability, in some cases, to extract the analytes from the packaged product without opening the package. For example, flavors present in wine can be checked before sale or purchase by introducing the fiber into the headspace of the wine through the cork of the bottle. Since only a small amount of flavor is extracted, the composition of the product does not change, and the extracting phase does not contaminate the product since the polymeric phase is nonvolatile and insoluble. A similar process can be applied to on-line product monitoring to assure the best possible quality.

Food and pharmaceutical products are frequently contaminated by volatile organic solvents, which are used in manufacturing and processing of these goods. Considering the frequent complexity of their matrices, the analytical procedures can be quite involved. Static headspace is frequently used for this purpose, but SPME has been found to be a good alternative for the analysis of both contaminated pharmaceuticals\(^{47}\) and foods\(^{48}\) because of its superior sensitivity, especially for less volatile compounds. Samples can be analyzed by dissolving the product in water prior to determination, or the analytes can be extracted directly from the headspace above the product. Typically, standard addition is used for quantitation. The DLs are similar to those obtained for environmental matrices.

Flavors constitute another very interesting topic for investigation. SPME has been applied for the analysis of a wide range of food products, spices, oils, beverages\(^{49,50}\) and even black and white truffle aroma.\(^{51}\) Initial investigations indicate that good quantitation of volatile analytes in the matrix can be obtained after the solid components of the sample matrix are separated from the aqueous phase by centrifugation. Combining SPME extraction with GC separation using chiral stationary phase, provides information not only about the composition of the products, but also their natural purity.\(^{52}\) Figure 24 shows the separation of peppermint oil (a) and peppermint-flavored candy (b) using a β-cyclodextrin column.

Another interesting application of SPME for the analysis of foods is to quantify caffeine in soft drinks.\(^{53}\) The most convenient quantitation method for this determination is based on isotopically labeled standards which are readily available. In addition to caffeine, flavor components can also be detected in the same chromatographic run.
SOLID-PHASE MICROEXTRACTION IN ENVIRONMENTAL ANALYSIS

Figure 24 Headspace SPME extraction and chiral GC analysis of (a) peppermint oil and (b) peppermint-flavored candy using a $\beta$-cyclodextrin column. Oven temperature program: $40^\circ$C for 2 min, then $40-220^\circ$C at $4^\circ$C min$^{-1}$. Peaks: 1, (--)-$\alpha$-pinene; 2, (+)-$\alpha$-pinene; 3, $\beta$-myrcene; 4, (+)-sabinene; 5, (--)-camphene; 6, (--)-$\beta$-pinene; 7, (+)-$\beta$-pinene; 8, $\alpha$-terpinene; 9, 3-carene; 10, (--)-limonene; 11, (+)-limonene; 12, ($\pm$)-$\beta$-phellandrene; 13, $\gamma$-terpinene; 14, cineole; 15, menthone; 16, (+)-menthol; 17, (--)-menthol; 18, isomenthol; 19, ($\pm$)-menthyl acetone.

The number of research reports on semivolatiles in foods is more limited, but the scope of potential applications is as broad as in the environmental area. One of the interesting applications is determination of herbicides in wines.\(^{(32)}\)

4.6 Clinical and Forensic Analysis

The major advantage of SPME for clinical and forensic applications is its portability, which might eventually be translated into on-site sampling followed by immediate analysis by portable instruments. This approach would allow better monitoring of a patient’s condition during treatment or therapy, and better preservation of a crime scene since the objects would not need to be removed for the analysis to be performed.

Monitoring of human health can be achieved by non-invasive SPME methods. For example, breath contains the headspace of blood. Therefore, characterization of volatile components present inside the human body can be accomplished by adapting the SPME device to breath analysis. Figure 25 presents an example of breath analysis.\(^{(34)}\) The DLs are at a low nanomol per litre level, which provides sufficient sensitivity for practical application of this approach to monitoring alcohol and acetone levels in blood. SPME can also be used for rapid analysis of body fluids. Figure 26 illustrates the detection of several aromatic amines in the milk of a mother who is a smoker.

Figure 25 SPME/GC/ITMS analysis of a breath sample. The sample was taken after alcohol consumption. Fiber coating: Carbowax™/DVB. Peak assignment: 1, acetaldehyde; 2, ethanol; 3, acetone; 4, isoprene; 5, carbon disulfide.

Figure 26 SPME/GC/ITMS analysis of human milk from a smoker. 1, aniline; 2, methylaniline; 3, dimethylaniline; 4, trimethylaniline; 5, nicotine.
Analysis for alcohol and drugs in body fluids is frequently performed in clinical and forensic laboratories. SPME is suitable for monitoring alcohol levels in both urine and blood. Drugs in body fluids are more difficult to analyze, since typically they are semivolatile substances. However, a number of published preliminary results indicate that headspace SPME analysis at an elevated temperature, or even direct extraction after dialysis of urine or blood serum, is possible. Most of the work to date was done with amphetamines, but analysis of other drugs, including valproic acid, cocaine, tricyclic antidepressants, nicotine and local anesthetics have been also reported.

In forensic analysis, headspace SPME has been applied for the examination of suspected arson cases. Figure 27 shows the total and selected ion chromatograms corresponding to a real arson sample and a gasoline standard, indicating the possibility of use of an accelerant.

4.7 Future Analytical Developments

SPME can be used as sampling and sample introduction technique for fast GC. Figure 28 demonstrates that using such an approach, volatile compounds in water can be analyzed in less than three minutes, approximately ten times faster compared to the currently used purge and trap systems.

SPME is very well suited for field analysis. Field sampling and analysis reduce the costs and eliminate many possible sources of error associated with handling and storing of the samples. In addition, field analysis enables faster and better characterization of the problems at hand since analytical information is available immediately for evaluation and decision. It has been demonstrated that SPME can be successfully used for fast GC analysis in the field with dedicated instrumentation. Also, time-average sampling as described in section 2 would facilitate wider adoption of SPME in the on-site field monitoring.

Ion-exchange coating materials and crown ether ligands have been used to selectively extract inorganic ions from aqueous matrices, allowing not only quantitation, but also speciation. Distribution of chemicals in complex samples can be characterized using SPME, as discussed in section 4.8, because of its equilibrium principle. Polyacrylic acid coating has been developed for the analysis of basic proteins. The small size of the fiber will allow speciation of minute sample volumes, for example down to single cell dimensions.

4.8 Physicochemical Applications

SPME can be applied not only for extraction purposes, but also to perform measurements which better characterize the extraction system. The measurements can
include studying the properties of the fiber coating and investigation of multiphase equilibria in the matrix. In addition, since detailed mathematical treatment of the process is available, SPME can be applied to study the parameters involved in the extraction, including diffusion coefficients in both the coating and the extracted phase, as well as various distribution constants.

For understanding solute–solvent interactions at the molecular level and the thermodynamic processes involved in forming the solution, the study of infinite-dilution activity coefficients of probe solutes in a polymer phase is a fundamental approach. SPME can be a useful tool for determining these coefficients. The stationary phases of interest can be coated on fibers made of suitable materials (fused silica, stainless steel, etc.). The SPME device with a selected coating can be used to extract a group of probe compounds, which are then separated on a standard commercially available column and quantified by GC/MS.

The SPME measurements of infinite-dilution activity coefficients of probe solutes in a selected stationary phase consist of two steps. The first step is to measure the infinite-dilution partition coefficients of the probe solutes between the stationary phase and the gas phase. Then, from these partition coefficients, the corresponding activity coefficients are determined.

Investigation of analyte distributions in natural systems is critical for many disciplines of science including environmental chemistry. Information gained during these studies is also very important to analytical chemists, since it facilitates the development of optimum sampling protocols and can lead to more rational optimization of extraction parameters. One approach to study multiphase equilibria involves separation of the individual phases after equilibrium has been reached and analysis of the individual phases to determine the concentrations of target compounds. For example, SPME was used to study the concentration of organic substances from octanol-saturated water. However, separation of the phases is not always necessary. SPME has been applied to measure the distribution of chemicals between the components of a system consisting of water and dissolved humic organic matter (HOM). Concentrations of the free forms of the target compounds were determined in pure water and water containing HOM. Based on a comparison of results obtained for the two samples, the partitioning of the analytes between water and HOM was determined. Good agreement was found between SPME and standard techniques, which indicates that it is well suited for such investigations.

Partitioning kinetics is another important issue for analytical chemists, since it determines the extraction rates. Interaction of nonpolar organic analytes with dissolved polymers is fast because physisorption does not require high activation energies. SPME can be used to investigate the kinetics of the equilibration process of organic pollutants between water and dissolved HOM. In such study the sample containing native analytes is spiked with isotopically labeled analogs. Rapid extraction from a stirred HOM–water sample can monitor concentration changes of target analytes with respect to time. Figure 29 illustrates the change of the concentration of labeled compound in water versus native analyte as a function of time. The curve indicates rapid equilibration of the species between water and HOM.

Soxhlet extraction is the removal and recovery of organic analytes from a permeable solid matrix by means of a solvent which is continually evaporated from a still-pot and condensed in such a manner that it falls into and permeates through the matrix which itself is held in a permeable container in a siphonable chamber. Soxhlet extraction has been used for over 120 years (since 1879) and is commonly used as a benchmark for total extractable organic residues.

Ultrasonic extraction is the removal and recovery of organic analytes from a permeable solid matrix by means of a solvent which is energized by sound energy at frequencies in excess of those audible to the human ear. Energy may be introduced into the sample by means of an ultrasonic probe which is inserted into the sample or an ultrasonic bath into which the sample plus solvent is immersed. The ultrasonic energy may be strong enough to disrupt and pulverize the matrix, thus increasing the extractability of the analyte.

The operation of the Soxhlet extractor is intuitively easy to grasp. Extraction is viewed as being complete or close to complete.

Ultrasonic extraction is convenient and straightforward. Ultrasonic baths provide relatively reliable sources of extraction energy.

Soxhlet extraction is solvent intensive and requires laboratory facilities in which flammable and toxic solvents can be used safely. The glassware required is expensive and vulnerable to breakage. Cooling of the condenser of the Soxhlet apparatus requires a constant supply of cooling water. Residues are concentrated in the still-pot and are thus vulnerable to thermal degradation. Only total residue can be extracted by Soxhlet extraction; little or no speciation is possible.

Ultrasonic extraction must be performed under conditions which protect the hearing of laboratory personnel. The ultrasonic generator may generate heat which may affect the extraction process. Ultrasonic probes become pitted when used for the extraction of abrasive matrices such as soil, thus changing the energy generated and affecting the extraction efficiency of the procedure. Ultrasonic baths provide less intense extraction energy. Extraction of total residue is the aim of ultrasonic extraction; little or no speciation is possible.

1 INTRODUCTION

Extraction techniques can have as their objective the extraction of all of the analyte, no matter what its environment in the sample, or the selective extraction of residues from defined environments within the sample matrix. Both Soxhlet extraction and ultrasonic extraction have as their goal the complete extraction of specified analytes or groups of analytes from solvent-accessible solid matrices. The methods are intended to be exhaustive, and performance that does not meet these expectations is usually viewed as being unsuccessful. In samples containing medium to high concentrations (>20 mg kg\(^{-1}\)) of
the analyte or analyte group, virtually all residue will be readily extracted; it is unlikely to be adsorbed in such a way that extraction is prevented. In relating low residue levels (<20 mg kg⁻¹) to toxicological interpretations, it is important to remember that all residues are not created equal. Those having the most significance toxicologically speaking are most often the freely available residues, the unassociated ones. Residues which are complexed, adsorbed, sequestered, or incorporated into a matrix either physically or covalently are less available or unavailable biologically, but are residues nonetheless. The degree to which the total residue is extracted from particular matrices will depend a great deal on the extraction conditions and the technique employed. Thus Soxhlet extraction may be carried out in conjunction with hydrolytic conditions to free residues conjugated with biological molecules or soil humic material. Ultrasonic extraction may need to be carried out with sufficient energy to assist the physical break-up of the matrix to free entrapped residues.

Soxhlet extraction is the removal and recovery of organic analytes from a permeable solid matrix by means of a solvent which is continually evaporated from a still-pot and condensed in such a manner that it falls into and permeates through the matrix which itself is held in a permeable container in a siphonable chamber. In Soxhlet extraction, the solvent is continuously purified and recycled and the extracted material is concentrated in the still-pot. Soxhlet extraction has been used for over 120 years and is commonly used as a benchmark technique for total extractable organic residues.

Ultrasonic extraction is the removal and recovery of organic analytes from a permeable solid matrix by means of a solvent that is energized by sound energy at frequencies in excess of those audible to the human ear. Energy may be introduced into the sample by means of an ultrasonic probe that is inserted into the sample or an ultrasonic bath into which the sample plus solvent is immersed. Officially recognized methods specify the former; however, the latter method has been used effectively, e.g. for herbicide residue extraction from soils.¹ The ultrasonic energy may be strong enough to disrupt and pulverize the matrix, thus increasing the extractability of the analyte. In ultrasonic extraction, the solvent remains with the sample and is heated only if sufficient energy is supplied to overcome heat dissipation at ambient temperature.

2 EXTRACTION METHODS

2.1 Soxhlet Extraction

Soxhlet extraction makes use of a three-piece apparatus (normally constructed of borosilicate glass) and a heat source. The still-pot, an appropriately sized round-bottomed flask, has a close-fitting joint to allow connection with the sample-holding siphonable chamber with solvent vapor by-pass tube, topped with the condenser unit (Figure 1). The heat source is usually an electric heating mantle sized to fit the still-pot. Early versions of this apparatus used drilled rubber or cork stoppers to join the sections; however, since the 1950s, Soxhlet extractors have been available with precision ground-glass joints to avoid escape of solvent vapors and to avoid contamination of the extract with material which is extracted inadvertently from the stopper matrix. Soxhlet apparatuses come in a variety of sizes from micro versions with 25-mL still-pots to gigantic pilot-plant scale milliliter-sized models. Custom construction is possible; however, the most common sizes are available from glassware suppliers and have 100- or 125-, 250-, 500-, or 1000-mL still-pots with the rest of the apparatus proportioned to fit; micro sized Soxhlet extractors are also now readily available and are suitable for the 1–5 g samples increasingly used to enable solvent volumes per sample to be reduced. Samples to be extracted are usually contained in paper or glass thimbles that fit inside...
the sample-holding chamber, although in special circum-
stances thimbles can be made of other inert materials
(e.g. Teflon® or stainless steel) as long as they have been
suitably precleaned and pose no risk of contamination
of the sample or sample extract. Thimbles are commonly
available from the same supplier as the apparatus itself.

Some Soxhlet procedures make use of flat-bottomed
still-pots such as Erlenmeyer flasks with hotplate heating
sources (e.g. AOAC (Association of Official Analytical
Chemists) Method 920.172, see Table 2).

Samples are placed in the thimbles and the tops are
protected with paper or glass-wool covers to prevent
splashing as the condensed solvent falls from the
condenser. To ensure compatibility with the extraction
solvent, the sample is often predried, pulverized, or mixed
with a filter-aid such as sand or Celite® to facilitate solvent
permeation. It may also be mixed with anhydrous sodium
sulfate (Na₂SO₄). The sample in the thimble must not
exceed the height of the solvent siphon (Figure 1).

Soxhlet extraction is described in the USEPA (United
States Environmental Protection Agency) Method
3540C as ‘a procedure for extracting nonvolatile and
semivolatile organic compounds from solids such as soils,
sludges, and wastes’ and one that ‘ensures intimate con-
tact of the sample matrix with the extraction solvent’. The
method is ‘applicable to the isolation and concentration
of water-insoluble and slightly water soluble organics’
and extracted analytes are then identified and quantified
usually by means of a chromatographic technique.

In order to render a solid matrix permeable to
the extracting solvent, one of two approaches may be
followed:

- The matrix is either air-dried to remove water, or
  it is mixed with the drying agent, anhydrous sodium
  sulfate, to sequester water prior to the placing of
  the matrix in the extraction thimble; the extraction
  solvent is immiscible with water.

- The matrix is extracted with the water in place but the
  extracting solvent is prepared to render it compatible
  with the water; usually a pair of miscible solvents is
  used, one of them being water miscible and the
  other not.

The first approach allows a water-immiscible solvent to
be used without fear of in situ water preventing contact
with residues sorbed or otherwise associated with the
matrix (e.g. soil). In view of the complex behavior of
soil matrices in the presence and absence of water,
it is often preferable to leave the water in place and
use the second approach. The drying action of the first
approach may intensify sorption of the analyte(s) to the
matrix and sometimes render the residues unextractable.
If it is important to determine the moisture content of
the sample, a portion of it should be taken for this
determination before the sample is dried or mixed with
the drying agent (see section 2.2.2).

Method 3540C specifies the use of a 500-mL still-pot;
however, the analyst would be well advised to modify
the method to allow the use of smaller scale extraction
providing that it is still compatible with the limits of
detection and quantification desired, and that the sample
being extracted is still representative of the matrix being
analyzed. The larger sample sizes are sometimes used to
compensate for sample inhomogeneity.

Extraction solvents used for Soxhlet extraction need
to be of sufficient purity that the extract is able to be
concentrated for subsequent steps without the impurities
interfering with the analysis. For process samples, reagent
grade solvent may be sufficient; however, environmental
matrices will require the use of high-purity distilled-in-
glass grade solvent. Typical solvents used are given in
Table 1.

Soxhlet extraction dates from the 1870s; however, many
approved standard methods of analysis incorporate this
extraction technique including a significant number of
the AOAC Official Methods (Table 2). This table is
extensive and the extraction methods are somewhat out of
date in that many use solvents no longer permitted for use
for occupational toxicological reasons, such as benzene
and chloroform. However, they remain official standard
methods of the AOAC in which Soxhlet extraction plays
an important role.

2.2 Ultrasonic Extraction

The ultrasonic procedure promotes intimate contact of
matrix and extraction solvent through energetic mixing
using intense ultrasound as the energy source.

Ultrasonic extraction can be conducted by one of
two procedures. Either an ultrasonic probe is used to
introduce ultrasonic energy into the mixture being

extracted, or the mixture in a glass container is immersed in an ultrasonic water bath. Although the energy introduced using the probe technique is of greater local intensity, some authors believe that the bath technique is more likely to provide consistent extraction results. Extraction of abrasive matrices such as soil or sediment using a probe can lead to erosion of the probe tip, resulting in loss of the ability of the probe to deliver sonic energy efficiently to the system being sonicated.

Ultrasonic extraction is regarded by the USEPA Method 3550 as being not as rigorous as other extraction methods for soils and solids. It is therefore of utmost importance that, if the method is used, the method and the manufacturer’s directions be followed carefully to achieve good extraction efficiency. Successful use of this extraction technique demands that the device has minimum power of 300 W and is equipped with the appropriate disrupter horn, tuned, and in good working condition. The horn tip must be inspected regularly for wear, as the shape of the horn tip will influence the effectiveness of the technique. The sample must be a free flowing powder, achieved for example by thorough mixing with anhydrous sodium sulfate prior to the addition of the solvent. The horns used for medium/high analyte concentrations are not interchangeable with those used for low concentrations.

The tip of the ultrasonic horn is positioned just below the surface of the extraction solvent, yet clear of the solid matrix material. Three extractions are performed with the apparatus in the specified pulse mode. Very active mixing of the slurry so produced should be observed during the procedure.

Recognized official methods using the ultrasonic procedure have been published by the AOAC (Table 3) and the USEPA (Table 4) with adjustments for the extraction of medium/high concentrations of analyte(s) and low concentrations in Table 5.

### 2.2.1 United States Environmental Protection Agency Method 3550 – Ultrasonic Extraction

This method is designed specifically for the extraction of nonvolatile and semivolatile organics from solids (soils, sludge, and wastes). Common solvents suitable for a variety of analytes are given in Table 4. Adjustments for medium-high or low concentrations of analytes are given

in Table 5. Sample handling is described in Table 6. The original method may be consulted for completeness.

### 2.2.1.1 Samples Containing Low Concentrations

For samples expected to contain low concentrations of organics (<20 mg kg\(^{-1}\)), the extraction procedure should be performed as quickly as possible to avoid losses of the more volatile extractables. Weigh approximately 30 g of sample to the nearest 0.1 g into a 400-mL beaker and add anhydrous sodium sulfate if necessary to yield a free-flowing matrix. Add 1.0 mL of the surrogate standard to all samples (samples, spiked samples, QC samples) and blanks. For appropriate surrogate compounds and concentrations, see section 4.2.

Add 100 mL extraction solvent to the sample in the beaker and place the bottom of the disrupter horn about 1.25 cm below the surface of the solvent, but above the solid on the bottom of the beaker. (Ensure that the ultrasonic system and horn have been properly tuned according to the manufacturer’s instructions.) Extract ultrasonically for 3 min with the output control set at full power, the mode switch on pulse, and the percentage duty cycle knob at 50% (energy on half of the time and off half of the time). Do not use the microprobe tip for samples containing <20 mg kg\(^{-1}\) of the analyte(s). The extract solution is decanted or withdrawn following centrifugation or filtered through Whatman No. 41 filter paper or equivalent (precleaning will be required for use with extracts of samples containing very low concentrations of residue) in a Buchner funnel under reduced pressure. The extraction will need to be repeated two or three times with additional portions of solvent (the USEPA method requires that these portions be 100 mL; however, the volume may be reduced to suit the circumstances if the residue is readily soluble in the extraction solvent). If filtration is being used, the final extraction is followed by transfer of the entire sample into the Buchner funnel with rinsing. Filtration should proceed until visible solvent has been removed from the filter-cake in the funnel. Do not attempt to completely dry the filter-cake as this action may result in the loss of the more-volatile analytes.

An attractive alternative if sufficient concentration of analyte(s) is present is to withdraw an appropriate aliquot of the total extract solution to carry through the rest of the procedure so that manipulation of the extract is simplified and losses are minimized.

### 2.2.1.2 Samples with High Concentrations

This refers to samples containing >20 mg kg\(^{-1}\). Accurately weigh 2 g of sample into a 20-mL vial and cap the cleaned mouth of the vial to prevent cross-contamination with other samples. Add 2 g of anhydrous Na\(_2\)SO\(_4\) and mix well in the vial. Add 1.0 mL of surrogate spiking solution to the

mixture. Add sufficient solvent to bring the final solvent volume up to 10 mL and sonicate the sample using the 3 mm tapered microtip probe for 2 min (output control level 5 and mode switch on pulse and 50% duty cycle; Table 7).

2.2.2 Determination of the Dry Weight of the Sample

If sample analytical results are to be expressed on a dry weight basis, a second portion of the sample should be weighed out (at the same time as the portion undergoing analysis). This 5- to 10-g subsample should be dried in a drying oven at 105°C overnight and then cooled in a desiccator before weighing.

Caution: Care should be taken to carry out the drying of contaminated samples in an oven contained in a well functioning fume cupboard. Significant contamination of the laboratory may result otherwise, and further low residue work in that laboratory may not be possible until the laboratory has been thoroughly decontaminated.

2.2.3 Concentration of Extract

Extract solutions may have to be concentrated (e.g. using a rotary evaporator under reduced pressure) or taken to dryness (e.g. with care under a stream of dry nitrogen) to facilitate exchange of solvent. Care should be taken to avoid volatile loss of analytes during this step.

3 METHOD DEVELOPMENT AND COMPARISON WITH OTHER EXTRACTION METHODS

3.1 Benchmark Methods for Comparison

Soxhlet extraction is itself a benchmark extraction method. A method suitable to be used for comparison to establish complete extraction is reflux in which the sample in a Soxhlet thimble is placed in a still-pot fitted with a condenser, or in which the sample is itself refluxed in the still-pot. The reflux technique ensures that the extraction takes place at the boiling temperature of the extracting solvent.

Ultrasonic extraction is usually evaluated by comparison with Soxhlet extraction as the benchmark.

3.2 Comparison Issues

Two comparison issues arise:

- does the new method extract as much total residue as the benchmark method;
- does the new method have speciation potential in that it does not extract total residue but extracts identifiable residue species such as unsorbed residues and/or reversibly sorbed residues.

Exhaustive extraction is intended to remove all residue of a particular analyte from the matrix. Both Soxhlet and ultrasonic extraction are methods of this type. Gentler, less energetic methods have the potential to extract selectively. For example, solid-phase extraction from water removes the freely dissolved residues of many organics, whereas residues associated with dissolved organic matter pass through; sediments can be filtered or centrifuged from water in which they are suspended.

Soxhlet and ultrasonic extraction have been compared with a number of other extraction techniques, often with Soxhlet extraction as the reference method. Examples are supercritical fluid extraction (SFE), high-pressure solvent extraction (HPSE), accelerated solvent extraction (ASE), i.e. extraction under increased pressure and temperature, and extraction with pressurized (subcritical) water at temperatures at or above 200°C. Tables 8 and 9 show several recent comparisons.

3.3 Extraction Variables

These include choice of solvent, temperature, and energy level.

3.3.1 Soxhlet Extraction

The extracting solvent ought to be a good solvent for the analyte(s) and a relatively poor solvent for the matrix and compounds of less interest. The more selective the extraction process, the fewer coextractives will have to be removed in a clean-up step.

The temperature used in Soxhlet extraction is related to the boiling point of the extraction solvent; however, by the time the solvent reaches the extraction thimble, it has been cooled somewhat in the condenser. Only if the Soxhlet extractor is of the type in which the thimble is suspended in the path of the vapor (i.e. there is no vapor by-pass tube, Figure 1d) will the actual temperature of the extraction thimble be maintained near that of the boiling solvent. Extracted material in the still-pot is thus refluxed...
in the extraction solvent. The material in the extraction thimble is heated somewhat because of its position above the still-pot. Thermally labile analytes will be vulnerable to degradation or charring if the extraction solvent boiling point is too high.

### 3.3.2 Ultrasonic Extraction

The major determining variable in ultrasonic extraction is the energy imparted to the extracting system by the ultrasonic transducer. Probe-type transducers are susceptible to damage from erosive substrates (e.g., sandy soil) and quickly lose their integrity. Bath-type extraction systems are more reliable, but the energy intensity available within the extraction system is usually much lower than that available with the probe-type set-up. Ultrasonic extraction is thus often not suitable for routine extraction where consistency over a period of time is required.

### 3.4 Making Use of the Data

Extraction data can be used for several purposes. Simple total residue data are suitable for compositional analysis in foods and agricultural products, pesticide residue analysis for regulatory purposes, and forensic analysis. However, analyses for toxicological or nutritional purposes should, take into account the biological availability of the analytes in the matrix being analyzed. Residues may exist in several forms:

- as freely dissolved entities;
- as entities associated with dissolved material such as dissolved organic matter in natural waters;
- as entities sorbed loosely (reversibly) with, for example, proteins or particulate organic matter in water;
- as irreversibly sorbed entities (includes covalently bound, ionically complexed, or physically entrapped residues).

The toxicologist needs to be able to distinguish between these types of residues to be able to interpret the analytical results intelligently. Chemical kinetics connects all of these residue types and their interconversion is controlled by these kinetics under the conditions prevalent at the time of interest; the freely dissolved residues are usually of acute toxicological importance. Other residues may be of importance if they can be converted to freely dissolved species, such as in the digestive tract. Therefore, total residue information will provide only crude correlation (if any) with toxicological effects, and analytical information allowing description of residues of each type is the most valuable to toxicology. Soxhlet and ultrasonic extraction techniques, therefore, may not be nearly as valuable to toxicologists as they are to others interested in chemical analysis.

4 QUALITY CONTROL AND TROUBLESHOOTING

#### 4.1 Data Quality Objectives

Extraction techniques require quality assurance procedures to establish that the extraction is reproducible and as complete as possible and that no systematic losses are
occurring during sample manipulation. Soxhlet and ultrasound extraction normally are checked for performance by the use of spiked samples, i.e. samples of the substrate to which a known amount of analyte has been added just prior to extraction.

Comparison of extraction methods is best carried out using standard reference materials (SRMs) or CRMs, if they exist. Sources include the National Research Council of Canada (NRCC), the Marine Analytical Standards Program, Halifax, NS and Ottawa, ON, Canada (toxaphene in carp homogenate and marine sediments), the US National Institute of Standards and Technology (NIST) in Gaithersburg, MD, USA (a variety of specific analyte/matrix combinations including toxaphene in cod liver oil), or the European Community Bureau of Reference (BCR) in Brussels, Belgium (SRMs which have been certified for PCBs). Sediment or soil SRMs are most reliably prepared from matrices contaminated with recalcitrant analytes in the field with concentrations of contaminants being determined by exhaustive extraction in the laboratory under carefully documented conditions.

SRMs are produced according to need, for example to back a regulatory system, or to serve a widespread measurement requirement, usually by request. They must of necessity be uniform such that a portion of the SRM supplied today will give the same answer under the same conditions as another supplied at another time.

When conducting interlaboratory studies relating to the measurement of environmental contaminants, an SRM and/or well characterized control material should ideally be included at the extraction step with every set of samples. The extraction technique is then used to see if the artificially introduced analyte can be recovered in a consistent manner. Surrogate standards are used to check for systematic losses.

To ensure that compounds which are present as part of the sample matrix do not interfere with the determination of the analytes being quantified, uncontaminated matrix control material is also analyzed. In some instances, the requirement for uncontaminated control material represents a great challenge for the analyst because, in many cases, there are often no easily obtainable samples of matrices which are entirely free of the contaminant(s).

### 4.2 Appropriate Surrogate Standards and Concentrations

A surrogate standard is a compound that is chemically similar to the analyte or analyte group but is not expected

|b| For analyte groups where no surrogate standard is listed, the analytical laboratory may choose one that fits the criteria given above. |
to occur in the sample itself. It is thus expected to behave like the analyte group, to be extracted to the same extent, and to be carried through the procedure in the same way as the analyte group. The surrogate standard should be added to each sample, blank, laboratory control sample, and matrix spike sample just before extraction commences. The recovery of the surrogate standard is determined to identify and quantify extraction efficiency and any other gross sample-processing errors and is evaluated on the basis of its measured concentration falling within acceptance limits. Recommended surrogates are given in Table 10.\(^{(12)}\)

**4.3 Matrix Spiking to Determine Extraction Efficiency**

A portion of uncontaminated analytical matrix, whether soil or agricultural product, is commonly spiked with the analyte dissolved in a solvent which can be subsequently easily removed. The introduced analyte is then allowed to associate with the matrix for a short period (hours) following which the extraction technique is applied and the residues determined. Spiking is almost always carried out with the analyte in solution, as accurate measurement of the quantity being spiked is made easier when the analyte is in solution. Determination of extraction efficiency \(E\) is can be calculated using Equation (1),

\[
E = \frac{\text{amount of analyte recovered} \times 100\%}{\text{amount of analyte spiked into sample}} \quad (1)
\]

**4.4 Coextractives and Contaminants**

Extraction of residues from matrices, particularly environmental matrices, is often accompanied by the extraction of other compounds with similar solubilities in the extraction solvent. Such compounds may be present in quantities far in excess of that of the analyte requiring their removal before instrumental analytical techniques can be used. Such clean-up techniques can be of similar difficulty to the extraction step itself.

The extraction solvent must also be free of contaminants as when the extract solution is reduced in volume to allow the next step in the analysis to take place, any contaminant present will also itself be concentrated. Such contaminants can then interfere with the analytical procedure by obscuring instrumental responses arising from the analyte(s) of interest.

**5 ENVIRONMENTAL APPLICATIONS**

**5.1 Applicable Matrices for Extraction by these Methods**

Environmental solids such as soil, sediment, finely divided wood, seeds, chopped or ground plant tissue, animal tissue ground with sodium sulfate, or oils supported on a sorbent are suitable for extraction by these methods. Recent work by Rahman et al.\(^{(11)}\) compared the extraction capability of six extraction methods for chlorobiphenyls in sewage sludge (CRM 392 containing PCBs CB-28, CB-52, CB-101, CB-118, CB-138, CB-153, CB-180) by the following methods (Table 9):

- Soxhlet–Dean–Starck with toluene;
- Soxhlet with hexane–acetone (2 : 3);
- cold digestion/saponification with 2 mol L\(^{-1}\) KOH in methanol followed by partition with hexane;
- sonicated liquid–solid extraction with hexane–acetone (1 : 1);
- cyclic steam distillation;
- column elution with dichloromethane.

Treatment of the CRM with BF\(_3\)/methanol and partitioning with dichloromethane gave results in close agreement with the certified values for all congeners. See Table 8 for further comparisons.

**5.2 Interface with Toxicology**

In environmental and biological applications, Soxhlet extraction has commonly been used to measure residues of toxicants including pesticide residues, industrial chemicals, and pharmaceutical drugs. Soxhlet extraction of necessity generates results that reflect total residue, i.e. no speciation of residues occurs. Ultrasonic extraction similarly cannot easily be used to distinguish between the various species of residues. As a result, these two extraction techniques generate results that are only of very approximate environmental use. They will virtually always overstate the concentration of residue with respect to the determination of toxicological risk (or conversely, lead to understatement of the toxicological potency of the residue where measured toxicity is related to total rather than available residue).

**5.3 Confounding Phenomena to be Considered**

Residues being quantified are usually present in a variety of forms: unassociated or freely dissolved in the interstitial water in a sediment or soil sample, loosely associated but not adsorbed to the matrix, associated with dissolved organic matter, reversibly sorbed to particulate matter or soil organic matter, or irreversibly sorbed to particulate matter or soil organic matter. It must be determined
whether the extraction method will remove all or just a portion (particular species) of the residue.

6 REGULATORY ISSUES

6.1 Value of Total Residue Data

In the case of analysis of residues at concentrations above 20 mg kg\(^{-1}\), total residue is very useful, because the sample is probably being analyzed for a food nutritional component (AOAC Methods 963.15 or 969.14) or for a gross contaminant such as petroleum hydrocarbons in soil.

At concentrations below 20 mg kg\(^{-1}\), total residue data are useful in that they represent ‘all of the residue’ of the analyte or analyte group in the matrix. These residues may be unassociated with the matrix, loosely associated with the matrix, reversibly bound to the matrix, or irreversibly bound to the matrix. For best results, a determination of each of these chemical species is required. Total residue determination by itself is just the beginning; residues so determined may in fact have little quantitative toxicological significance.

6.2 Relationship between Solvent-extractable Residue and Toxicology

Solvent-extractable residues at low concentrations can only very approximately be used to predict toxicological responses in natural systems. The most readily extracted residues (the ‘available’ residues) are probably the ones most directly correlated with toxicological response; however, imitating the conditions present in environmental or physiological samples is very challenging, perhaps impossible. In general, no speciation of residues is effected with either Soxhlet or ultrasonic extraction. Techniques other than the above described extraction procedures may have to be used to generate speciation data. Some speciation data may in some cases be determined by difference if they cannot be ascertained directly. If bound residues are present, however, then more vigorous extraction may be required to generate total residue data; high-temperature subcritical water extraction, microwave-assisted extraction, or ASE may be required.

6.3 New Improved Soxhlet Extraction Methods

The Soxhlet extraction method is a long-established technique that has been improved over the years by the development of apparatus allowing more convenient use of the method. The addition of ground glass joints (Figure 1) was a major step forward and one that allowed analysis of trace and ultratrace residues to be conducted using Soxhlet extraction. Prior to the use of ground glass joints, contamination of the extract with coextractives derived from the cork or rubber stopper material would have prevented such application of Soxhlet extraction. Banks of Soxhlet extractors have been used in routine analytical laboratories facilitating the extraction of multiple samples. An automated Soxhlet extraction method has been established as a USEPA method (Method 3541). In this method, a commercially available three-stage extraction system is used to perform the same task in a shorter time. The stages are the following:

1. The extraction thimble containing the sample is immersed in the boiling solvent. The sample remains in intimate contact with the solvent and the analytes are extracted.
2. The thimble is elevated above the solvent and extracted in the ‘normal’ mode to free the sample of entrained extract.
3. The solvent is evaporated as would occur in a Kuderna–Danish concentrator.

A more recent development has added focused microwave heating to a Soxhlet extraction apparatus. Although Soxhlet extraction is one of the oldest extraction methods in use today, it continues to evolve.

6.3.1 Advantages

In Soxhlet extraction the operation of the extractor is intuitively easy to grasp. Extraction is performed in a visible manner and is seen as being complete or close to complete by its very nature.

Ultrasonic extraction is convenient and straightforward. Ultrasonic baths provide relatively reliable sources of extraction energy.

6.3.2 Limitations

Soxhlet extraction is solvent intensive and requires laboratory facilities in which flammable and toxic solvents can be used safely. The glassware required is expensive and vulnerable to breakage. Cooling of the condenser of the Soxhlet apparatus requires a constant supply of cooling water. Residues are concentrated in the still-pot and are thus vulnerable to thermal degradation. Only total residue can be extracted by Soxhlet extraction; little or no speciation is possible.

Ultrasonic extraction must be performed under conditions which protect the hearing of laboratory personnel. The ultrasonic generator may generate heat that may affect the extraction process. Ultrasonic probes become pitted when used for the extraction of abrasive matrices such as soil, thus changing the energy generated.
and affecting the extraction efficiency of the procedure. Ultrasonic baths provide less intense extraction energy. Extraction of total residue is the aim of ultrasonic extraction; little or no speciation is possible.

1 INTRODUCTION

SFE has become an attractive alternative to conventional solvent extraction for the recovery of organic compounds from both environmental and biological matrices. The high diffusivity, low viscosity, and variable solvent strength are some of the attractive features of SF. Carbon dioxide is the most common fluid for SFE. The moderate critical temperature (31°C) and critical pressure (73 atm (1 atm = 14.696 psi = 0.10132 MPa)), chemical inertness, low cost, and wide availability in pure form are a few of the advantages of supercritical CO2. Most of the studies in the literature (~95%) regarding SFE have dealt with organic compounds.

Different research groups have investigated extraction of metal ions from environmental matrices using either pure or modified supercritical CO2 as an extraction fluid. It is known that cationic metal ions are not soluble in pure CO2 due to weak interactions between the positively charged metal ion and the relatively nonpolar CO2.

Therefore, it could be concluded that extraction and separation of metal ions via supercritical CO2 are not feasible. However, metal ions may be solubilized, extracted, and separated via binding them to an organic ligand, which results in the formation of a neutral stable metal complex that exhibits solubility in SFs. Rapid complexation kinetics between the metal ion and ligand and a high stability constant for the resulting neutral complex, can obviously enhance the extraction process. The efficiency of extraction is dictated by four different factors:

1. ligand solubility in the SF
2. reaction rate of ligand with metal ion in the SF
3. solubility of metal chelate in the SF
4. stability of ligand and metal chelate in the SF.

2 SOLUBILITY OF CHELATING AGENTS AND METAL CHELATES

Two techniques (dynamic and static) have been used to measure the solubility of ligands and metal chelates in SFs. In the dynamic case, a solute is continuously, but slowly swept with SF. The solubility is measured based on the weight of analyte dissolved in an exact volume of fluid.

With this technique, the solubility would be expressed in moles of analyte per liter of SF at a given density. The solubility is also commonly reported as the mole fraction of analyte, wherein moles of SF can be obtained from the volume and density. In this procedure, the solubility may depend on the flow rate of fluid passing by the analyte. Ashraf-Khorassani et al. have demonstrated that solubility of ethyl centralite (I) not only depends on
pressure and temperature, but is also a function of \( \text{CO}_2 \) flow rate through the extraction cell. Their results showed that at low flow rate, solubility was greater because the system was closer to equilibrium conditions, while at higher flow rate solubility was lower.

\[
(C_2H_5)NH \overset{O}{-} C - NH(C_2H_5)
\]  

(1)

In the static mode, the cell is loaded with a known amount of solute and SF at a known density. Usually, equilibrium between solute and SF is achieved using either recirculation or diffusion to homogenize the fluid. Analysis in this case is usually accomplished by using a spectroscopic method such as ultraviolet (UV) spectroscopy. This technique is convenient since the analysis is in situ and equilibrium can be obtained easily. However, the effect of the SF on the spectral absorption properties of the analyte and the bandshape of the solute complicate these measurements. In addition, adsorption of the solute onto the UV or IR (infrared) cell window from the saturated solution may occur, yielding incorrect results. In the static diffusion mode after system pressurization is attained, the solute is allowed to diffuse into the SF for a certain period of time in order to establish equilibrium between the solute and SF. After equilibrium is established, the cell is depressurized and the analyte dissolved in the SF is collected in an organic solvent outside the vessel. The solubility of an analyte in this case can be measured using either gravimetric

Figure 1 Solubility measurement apparatus.
or spectroscopic methods. Although often used, this technique has several pitfalls including (1) equilibration by diffusion may take more than 1 or 2 h, (2) precipitation of the analyte on the top and inside the extraction tube may occur during depressurization, and (3) the restrictor may plug due to the high concentration of analytes in the decompressing fluid.

Ashraf-Khorassani et al. (3) used on-line SFE/HPLC (high-performance liquid chromatography) to measure the solubility of different metal β-diketonate complexes in supercritical CO2. Figure 1 shows a schematic of the system used to determine the solubilities. In each measurement, the 0.5 mL extraction vessel was filled with a metal chelate. Next, the system was pressurized to 200 atm using pure CO2. After pressurization of the system, the three-way valve was rotated such that the solubilized chelate in supercritical CO2 was directed from the 1 µL loop to the HPLC system (Figure 1b). The HPLC flow then washed the chelate from the injection loop through the column to a variable-wavelength UV absorbance detector operated at appropriate wavelength. By employing a second valve (six-port two-position valve), a stream of carbon dioxide or air could then pass through the sample loop to remove the chromatographic mobile phase from the loop, thus avoiding modification of SF composition (Figure 1c). The four-port two-position valve could then be rotated back to the load position and the procedure repeated (Figure 1d).

This system had several advantages compared with systems used previously. First, solubility measurements were obtained in an organic solvent not under SF conditions, eliminating spectral shifts. Second, complete equilibration between solute and SF was achieved via a recirculation pump. Finally, replicate measurements can be obtained without recharging the vessel with CO2 or analyte.

Solubility of the metal chelate in supercritical CO2 is the key factor in SFE of metals. In this respect, different types of ligand have been used for complexation and extraction of trace metals in supercritical CO2. The literature, however, regarding the solubility of metal chelates in supercritical CO2 is very limited.

### 2.1 β-Diketones

In 1991, M’Hamdi et al. (1) measured the solubility of β-diketonate complexes of Cu2+, Y3+, and Ba2+ (i.e. the β-diketone was either acetylacetonate anion (AcAc) (2) or hexafluoroacetylacetonate anion (HFA) (3)), in supercritical CO2 at different pressures and temperatures. Solubility measurements were based on the weight of solute lost from the extraction cell and the mass of CO2 that passed through the extraction system. In this study, HFA complexes showed higher solubility in supercritical CO2 than the AcAc complexes.

![Chemical Structures](attachment:chemical_structures.png)

Wai and co-workers used the static mode with a 30 min equilibrium time to measure the solubility of lanthanum and europium 2,2-dimethyl-6,6,7,8,8,8-heptafluoro-3,5-octandione (FOD) (4), (La(FOD)3 and Eu(FOD)3) in supercritical CO2. (4) Analysis of the collected material was obtained via neutron activation analysis. The reported solubility of La(FOD)3 was approximately 2–3 orders of magnitude higher than that obtained for metal–AcAc complexes. The high solubility of La(FOD)3 in supercritical CO2 was related to the fact that FOD forms thermally stable and highly volatile complexes (La(FOD)3 = (5.5 ± 0.2 × 10⁻² M and Eu(FOD)3 = 7.9 ± 0.2 × 10⁻² M).

![Chemical Structures](attachment:chemical_structures.png)

Ashraf-Khorassani et al. (3) measured solubility of different metal AcAc and metal HFAs in pure CO2. In this study solubility of metal HFAs was found to be 2–3 orders of magnitude higher than the solubility of metal AcAcs in keeping with the earlier study of M’Hamdi et al. (1) (Table 1).

### 2.2 Dithiocarbamates

The first report on solubility of metal diethylthiocarbamate (DDC) (5) and bis(trifluoroethyl)dithiocarbamate (FDDC) (6) complexes was published by Laintz et al. (5) They measured the solubility of Ni(DDC)2, Ni(FDDC)2, Co(DDC)3, Co(FDDC)3, Cu(DDC)2, Cu(FDDC)2, Na(DDC), Na(FDDC), Bi(DDC)2, and Bi(FDDC)2 in supercritical CO2. A high-pressure view cell connected to an ultraviolet/visible (UV/VIS) spectrometer was used to measure the solubility of the metal chelates (Figure 2). In order to assure equilibrium between the analyte and the SF, a magnetic stirrer coated with Teflon™ was placed in...
by decompressing the fluid into a collection vial containing dissolved analyte were removed from the extraction cell under static conditions. Following this period, the fluid and undissolved analytes was removed from the extraction cell by decompressing the fluid into a collection vial containing 5 mL of chloroform. After complete depressurization of the extraction cell, the glass tube containing the undissolved analyte was removed from the cell. Next, the empty extraction cell was flushed with excess high-density CO₂. Any metal complex that may have been flushed out of the cell during this process was also collected.

Wai et al.⁶ in another study used a known amount of metal complex placed in a glass tube where both ends were plugged with glass wool. The sample tube was then placed in an extraction cell and pressurized to 150 atm. The cell was heated for 30 min at 60°C under static conditions. Following this period, the fluid and dissolved analyte were removed from the extraction cell by decompressing the fluid into a collection vial containing 5 mL of chloroform. After complete depressurization of the extraction cell, the glass tube containing the undissolved analyte was removed from the cell. Next, the empty extraction cell was flushed with excess high-density CO₂. Any metal complex that may have been flushed out of the cell during this process was also collected.

The solubility of the metal complex was measured based on the amount of metal complex dissolved in CO₂ of known density and volume equal to that of the extraction cell, the glass tube containing the metal chelates in supercritical CO₂ (Table 2). The solubility of metal chelates was found to have approximately 2–3 orders of magnitude higher solubility than the comparable DDC metal chelates (Table 2).

* 1 atm = 14.696 psi = 0.01032 MPa.

Ashraf-Khorassani and Taylor\(^{(7)}\) used an on-line SFE/HPLC system to measure the solubility of mercury bis(diethyl)dithiocarbamate (Hg(DDC)\(_2\)) and bis(bis(tri-fluoroethyl)dithiocarbamate) (Hg(FDDC)\(_2\)) complexes. Fluorination of the ligand increased the solubility of Hg(FDDC)\(_2\) at least an order of magnitude compared with Hg(DDC)\(_2\). Results obtained in this study indicated greater solubility than that reported by Wai et al.\(^{(6)}\) These differences were attributed to losses of analyte during depressurization of the CO2.

\[ \text{C}_8\text{H}_{17} \text{N} - \text{C} - \text{SH} \quad \text{C}_8\text{H}_{17} \text{N} - \text{C} - \text{SH} \]  
(7) \quad (8)

Wang et al.\(^{(8)}\) used the static mode to measure the solubility of zinc dibutylthiodithiocarbamate (Zn-DBDC) \((7)\), Zn(DDC)\(_2\), and Zn pyrrrolidine dithiocarbamate (Zn-PDTC) \((8)\) complexes (Table 3). In this study, 0.5–0.8 g of test complexing agent contained in a cardboard thimble was placed inside the extraction cell. After 30 min under static conditions, the cell was decompressed and the analyte was trapped in methanol, which was subsequently analyzed spectrophotometrically at 298 nm. The solubility of the zinc chelates in most cases increased with increasing hydrocarbon chain length.

Wai et al.\(^{(9)}\) performed a similar study to measure the solubilities of Cu\(^{2+}\), Hg\(^{2+}\) and Zn\(^{2+}\) complexes with seven different dithiocarbamate ligands (PDTC, DBDC, DDC, P3DC (dipropylthiodithiocarbamate) \((9)\), P5DC (dipentylthiodithiocarbamate) \((10)\), DHC (dihexyldithiocarbamate) \((11)\), and FDDC), in supercritical CO\(_2\) at 60°C and two different pressures (100 and 230 atm). They found that dithiocarbamate ligands with a small Hildebrand solubility parameter value yielded metal complexes that exhibited higher solubilities in supercritical CO\(_2\) (Table 3). For example, PDTC with a solubility parameter of 11.43 cal\(^1\)/cm\(^3\)/2 (1 cal = 4.1845 J) formed a copper complex (Cu(PDTC)\(_2\)) which had a solubility of 4.1 × 10\(^{-7}\) M in supercritical CO\(_2\) at 60°C and 100 atm while FDDC with a solubility parameter of 8.75 cal\(^1\)/cm\(^3\)/2 formed a copper complex (Cu(FDDC)\(_2\)) which had a solubility of 9.1 × 10\(^{-3}\) M under identical conditions.

### 2.3 Organophosphorus Reagents

Organophosphorus reagents are well known ligands for extraction of actinide series elements. Supercritical CO\(_2\) has shown promise for extraction of uranium from both solid and liquid matrices by complexation with organophosphorus ligands via in situ chelation. The first report on solubility of tributylphosphate (TBP) \((12)\) was by Page et al.\(^{(10)}\) They determined that 11% of TBP is miscible with CO\(_2\) at 60°C and 120 atm. Later, Schmitt and Reid.\(^{(11)}\) and Lin et al.\(^{(12)}\) reported solubility of other phosphine oxides (i.e. TBP, tributylphosphine oxide (TBPO) \((13)\), tri-n-octylphosphine oxide (TOPO) \((14)\), and triphenylphosphine oxide (TPPO) \((15)\) in...
supercritical CO$_2$ at different temperatures and pressures. It was determined that TBPO has high solubility in supercritical CO$_2$ at 200 atm and 60 °C, while the solubility of TPPO using the same conditions was at least two orders of magnitude lower. Solubility of TOPO was an order of magnitude lower than TBPO and an order of magnitude lower. Solubility of CMPO at 60 °C and 20 MPa was 0.41 mol L$^{-1}$, and solubility of CMPO at 60 °C and 20 MPa was 0.089 mol L$^{-1}$.

### 2.4 Other Chelating Agents

Wang et al.$^{(15)}$ used the static technique to measure the solubility of three different bistriazolocrown ether ligands (16, 17) and (18) in both pure and 5% methanol-modified CO$_2$. Solubilities of these crown ethers increased by an order of magnitude in 5% methanol-modified CO$_2$ compared with 100% CO$_2$ (Table 4). These ligands were used for direct in situ chelation of Hg$^{2+}$ and Au$^{3+}$ from both solid and liquid matrices. The solubility of these metal chelates was not measured.

Cowey et al.$^{(16)}$ used dynamic conditions to measure the solubility of 5,7,12,14-tetramethyl-2,3,9,10-dibenzo[b,i][1,4,8,11]tetraazacyclotetradecine-nickel(II) in supercritical CO$_2$ and 10% methanol-modified CO$_2$ at different pressures (160, 250, and 340 atm) and temperatures (40, 50, 60, and 70 °C). The solubility of each analyte was measured by comparing the amount of extracted analyte that was collected with a certain volume of pure or methanol-modified supercritical CO$_2$. The Ni complex solubility, in 10% methanol-modified CO$_2$, varied from 7.2 × 10$^{-6}$ to 5.77 × 10$^{-5}$ g mL$^{-1}$ depending on the pressure or temperature of the operation (Table 4). They

3 CHELATING AGENT STUDIES

The ligand used for SFE of metal ions is of primary importance. The solubility, rate of formation, and stability of metal chelates dictate the success of extraction of metal ions from their environment via SFE. Inorganic SFE of metal ions and chelates will be presented with respect to the ligand used for extraction.

### 3.1 \( \beta \)-Diketones

Several research groups have demonstrated extraction of metal ions from different matrices using various \( \beta \)-diketones. Extraction of lanthanides and actinide series ions has received considerable attention from several research groups. SFE of lanthanides and actinides was first reported by Lin et al.\(^3\) In their report, the extraction of \( \text{La}^{3+} \), \( \text{Eu}^{3+} \), \( \text{Lu}^{3+} \), and uranyl (\( \text{UO}_2^{2+} \)) ions was performed from both wet and dry cellulose-based filter paper using pure and methanol-modified \( \text{CO}_2 \). In each extraction, filter paper was spiked with 10 \( \mu \)g of lanthanide or actinide ion and 20 \( \mu \)L of 80 mmol of FOD was placed in the extraction cell. The chelation and solubilization processes were allowed to occur under static SFE conditions for 10 min. A wet sample was prepared by spiking 10 \( \mu \)L of water onto the filter paper. Following extraction, decompression, and collection of the analyte in chloroform, the lanthanides were back-extracted with 50% \( \text{HNO}_3 \) solution followed by neutron activation analysis of the acid solution. An extraction efficiency of less than 20% was obtained for \( \text{La}^{3+} \), \( \text{Eu}^{3+} \) and \( \text{Lu}^{3+} \) using...
pure CO₂ from a wet matrix. However, the recoveries increased to above 65% and 90% from dry and wet matrices, respectively, using 5% methanol-modified CO₂. In a similar fashion the extraction efficiency of uranyl ion spiked onto filter paper was studied. The extraction of [(UO₂)²⁺] using 5% methanol-modified CO₂ containing FOD at 60°C and 150 atm from either dry or wet matrix yielded recoveries above 95%.

Lin and co-workers(17,18) have used other fluorinated β-diketones (e.g. HFA, thenoyltrifluoroacetone (TTA) (19), and trifluoroacetylacetone (TAA) (20)) for extraction of lanthanides and actinides using both pure and 5% methanol-modified CO₂. The extraction efficiency of La³⁺, Eu³⁺, and Lu³⁺ from cellulose-based filter paper using pure supercritical CO₂ saturated with different fluorinated β-diketones was less than 25%. However, the extraction efficiency of the same lanthanides using 5% methanol-modified CO₂ saturated with the same fluorinated ligands varied from 11–95% depending on the ligand.

The effect of the matrix on lanthanide extraction was also investigated. A topsoil sample was spiked with 10µg each of La³⁺, Eu³⁺, and Lu³⁺.(17) The sample was extracted with neat CO₂ containing a mixture of TBP and one of the fluorinated β-diketones (i.e. HFA, TTA, or FOD). Results showed that the best extraction efficiency of lanthanides (80, 88, and 92%) was obtained using a mixture of TBP and HFA. Furton et al.(19) determined the extraction efficiency of uranium spiked onto solid matrices (e.g. polyester, glasswool, cotton, and Kaolin) via synergistic in situ chelation using pure and modified CO₂. They concluded that SFE yielded higher recovery than conventional liquid extraction. In their study, high extraction recovery of uranium was obtained via 5% ethanol with 0.10 M FOD- and 0.10 M TBP-modified supercritical CO₂.

Ashraf-Khorassani et al.(4) demonstrated extraction of different metal AcAc and metal HFA from an aqueous environment. Both metal AcAc and HFA complexes showed low extraction efficiency from water, although both complexes exhibited high solubility in pure CO₂. These results demonstrated that the extraction of metal chelates is not only solubility dependent, but also depends on the stability of chelates in the specific environment under supercritical conditions.

The sample was dissolved in water.

3.2 Carbamates

By far the greatest amount of research has focused on the use of carbamate ligands for the SFE of metal ions from both solid and liquid matrices. Carbamates, especially fluorinated carbamates, have both the good solubility and the stability needed for successful SFE. Carbamates have also been used for in situ derivatization of free metal ions in a variety of matrices.

Laintz et al.(20) have extracted Cu²⁺ spiked onto Celite. Extraction efficiency of Cu²⁺ using FDDC, however, did not exceed 80% at a CO₂ density of 0.70 g mL⁻¹ and 35°C. Later, Wai et al.(6) reported extraction of mercuric ion (Hg²⁺) from cellulose-based filter paper using Li(FDDC) as a chelating agent. In this experiment 10µg of Hg²⁺ was spiked onto filter paper. Then 10 mg of Li(FDDC) was added directly to the extraction vessel, thus creating a large excess of ligand relative to the mercuric ion. The extraction efficiency of Hg²⁺ was less than 12% for a dry sample. The low extraction efficiency of mercuric ion was thought to be due to a strong interaction between Hg²⁺ and the cellulose matrix. However, the addition of a small amount of water (10 µL) onto the matrix increased the extraction efficiency of mercuric ion to 84%. The extraction efficiency of Hg²⁺ was further increased from 84–95% with the use of 5% methanol-modified CO₂. This increase in extraction efficiency was stated to be mostly due to enhanced interaction between Hg²⁺ and the solvent modifier.

 Extraction of other heavy metal ions has been achieved using Li(FDDC) as a chelating agent. Liu et al.(21) reported extraction of Co³⁺, Cd²⁺, Zn²⁺, and Cu²⁺ from solid matrices (sand, soil, and filter paper) using supercritical CO₂ saturated with Li(FDDC). Metal ion recovery ranged from 70–100%. Extraction efficiencies were determined using gas chromatography (GC)/atomic emission detection. They reported that metal impurities in the stainless steel extraction vessel could react with the ligand and positively affect the percentage recovery of analyte. They suggested using a non-metal-containing vessel such as polyether ether ketone (PEEK) which cannot affect extraction efficiency of metal ions.

Wai(22) have reported extraction of both divalent and trivalent metal ions from spiked cellulose-based filter paper and sand. Extraction efficiency of greater than 90% was reported for Cd²⁺, Cu²⁺, Pb²⁺, Pd²⁺, Zn²⁺, As³⁺, Au³⁺, Ga³⁺, and Sb³⁺ from sand and filter paper using Li(FDDC) ligand. Wang and Marshall(23) have separated and characterized Cd²⁺, Zn²⁺, and Cu²⁺ bound to metallothionein (MT), isolated from rabbit liver samples, using supercritical CO₂ saturated with tetrabutylammonium dibutylthiocarbamate (TDBDC) ligand. Quantitative recovery of Cd²⁺ was obtained if MT was dissolved in water.
Laintz et al.\(^{(20)}\) have been able to extract Cu\(^{2+}\) ion quantitatively from an aqueous sample using supercritical CO\(_2\) saturated with Li(FDDC). In their experiment, supercritical CO\(_2\) was passed through a 10 mL stainless-steel vessel filled with solid Li(FDDC), which functioned as a ligand extraction vessel. Next, the supercritical CO\(_2\) saturated with Li(FDDC) was introduced into a high-pressure view cell filled with 5 mL of aqueous Cu\(^{2+}\) solution. The reaction of Cu\(^{2+}\) ion with Li(FDDC) was monitored at 416 nm (e.g. the charge-transfer absorbance band of Cu(FDDC)\(_2\)) via UV/VIS spectroscopy as a function of time. The rate of extraction of Cu\(^{2+}\) at different densities (constant temperature, 35 °C) and different temperatures (constant density, 0.22 g mL\(^{-1}\)) was studied. This was the first report of direct extraction of a metal ion from an aqueous solution using in situ chelation SFE. The extraction efficiency of Cu\(^{2+}\) ion was greater than 95% at densities above 0.35 g mL\(^{-1}\) and 35 °C. Extraction of Hg\(^{2+}\) ion from water was achieved with 5% methanol-modified CO\(_2\) and tetrabutyl-substituted dibenzobistriazolo-crown ether (Crow 11) \(^{(18)}\) at 200 atm and 60 °C.\(^{(9)}\) The extraction efficiency of Hg\(^{2+}\) was dependent on the amount of ligand placed in the ligand extraction vessel. It was determined that at least 10 mg of ligand is necessary for the extraction of 5 ppm Hg\(^{2+}\) from 4.5 mL of contaminated water.

Wai\(^{(22)}\) has reported extraction of both divalent and trivalent metal ions with CO\(_2\) from an aqueous matrix using Li(FDDC) as a ligand. An extraction efficiency of greater than 90% was reported for Cd\(^{2+}\), Cu\(^{2+}\), Pb\(^{2+}\) and Zn\(^{2+}\) from aqueous solution. In their study, after SFE the metal chelates were back-extracted from the collection solvent (chloroform) using nitric acid and analyzed via inductively coupled plasma mass spectrometry (ICP/MS).

Recently, Wang and Marshall\(^{(16)}\) used TDBDC ligand for in situ chelation SFE of Zn\(^{2+}\), Cd\(^{2+}\), and Pb\(^{2+}\) from aqueous media. Again supercritical CO\(_2\) was passed through a vessel which was filled with the diethiocarbamate. The saturated supercritical CO\(_2\) then passed through the aqueous phase contaminated with heavy metals. Following extraction and collection of the metal chelates, flow injection analysis coupled with atomic absorption spectrometry (FIA/AAS) was used to analyze and quantify the metals. Recoveries of ions from aqueous solution were \(\approx 73\%\) and \(\approx 94\%\) within 5–15 min, respectively. Different diethiocarbamates such as TDBDC, DDC, and PDTC were compared for extraction of Zn\(^{2+}\) ion. The extraction efficiency of Zn-DDBC was much greater than Zinc-diethylthiocarbamate (Zn-DDC) or Zn-PDTC. The high extraction efficiency of Zn-DDC was related to the high solubility of the chelate, since the solubility ratios of Zn-DDBC/Zn-DDC and Zn-DDBC/Zn-PDTC were 20 and 139, respectively.

Ashraf-Khorassani et al.\(^{(4)}\) demonstrated extraction of different metal DDC and metal FDDC from an aqueous environment. Metal FDDC complexes exhibited much higher extraction efficiency than metal DDC via supercritical CO\(_2\) using identical extraction conditions. They demonstrated that the extraction of metal DDC complexes is solubility dependent, while extraction of metal ions via in situ chelation is not only solubility dependent, but also depends on the stability of chelate under supercritical conditions. Toews et al.\(^{(24)}\) studied the influence of pH on the SFE extraction efficiency of metals and ionizable organic species in water. They concluded that metal extraction by in situ chelation is pH dependent. The pH of water ranged between 2.80 and 2.95 at pressures of 70–200 atm CO\(_2\) and temperatures between 25–70 °C. Therefore, any ligand that forms a stable neutral complex with metal ions at pH 3 should be useful in SFE.

Ashraf-Khorassani and Taylor\(^{(7)}\) have also investigated the extraction of mercury ions from a variety of matrices (soil, fly ash, sludge, filter paper, and sand) using DDC and FDDC as chelating agents. Using inert matrices, such as sand, both Hg(DDC)\(_2\) and Hg(FDDC)\(_2\) produced high recoveries. However, with active matrices (e.g. fly ash and sludge), Hg(FDDC)\(_2\) was much more efficient, producing recoveries greater than 95%, while Hg(DDC)\(_2\) was less than 60% efficient. In situ chelation of Hg\(^{2+}\) using Li(FDDC) as a chelating agent produced greater than 80% recovery from sand, filter paper, soil, and fly ash, but less than 60% from sludge.

### 3.3 Crown Ethers

Research has also been done using crown ethers as chelating agents for metal-ion extraction. Bistriazolo-crown ethers \(^{(16, 17, 18)}\) have been used for extraction of Hg\(^{2+}\).\(^{(15)}\) Five percent methanol-modified CO\(_2\) saturated with tetrabutyl-substituted dibenzobistriazolo-crown ether \(^{(18)}\) was found to extract only 78% of Hg\(^{2+}\) from sand, while the same fluid in the presence of 10 µL of water improved extraction efficiency to more than 95%. The high extraction efficiency of Hg\(^{2+}\) in the presence of water was related to a higher modified fluid–solution interaction. Tetrabutyl-substituted dibenzobistriazolo-crown ether was also used for extraction of similar heavy metal ions (Cd\(^{2+}\), Co\(^{3+}\), Pb\(^{2+}\), Ni\(^{2+}\), Mn\(^{2+}\), Au\(^{3+}\), and Zn\(^{2+}\)) from sand and filter paper.\(^{(15)}\) Extraction efficiencies of most metal ions other than Au\(^{3+}\) from wet matrices were less than 4% even when using 5% methanol-modified CO\(_2\). The efficiency of extracted Au\(^{3+}\) from wet filter paper using 5% methanol-modified CO\(_2\) was 79%.

Another chelating agent such as fluorinated crown ether carboxylic acid \((sym\text{-difluorobenzene-crown-5-oxacyclic acid})\) was also used for SFE of lanthanides.
and uranyl ion.\textsuperscript{(3)} SFE of lanthanides and uranyl ion using 5\% methanol-modified CO\textsubscript{2} saturated with sym-difluorobenzo-16-crown-5-oxyacetic acid in the presence of water at 60 $^\circ$C and 150 atm was less than 7\%.

### 3.4 Phosphines

Different phosphines, including tributylphosphine, have found some use as chelating agents. Phosphines have been used both as primary ligands and also for their synergistic effect when used in conjunction with other ligands.

SFE of lanthanides has been investigated using phosphine ligands. Lin and Wai\textsuperscript{(17)} studied extraction of La\textsuperscript{3+}, Eu\textsuperscript{3+}, and Lu\textsuperscript{3+} from buffered acetate solution at pH 4.0. Maximum extraction efficiencies of lanthanides (ranging from 75 to 89\%) were obtained with supercritical CO\textsubscript{2} containing TTA and TBP at 150 atm and 60 $^\circ$C. Extraction efficiencies of ions with supercritical CO\textsubscript{2} containing only TTA or TBP were poor. Extraction of uranyl and thorium ions from water was also performed.\textsuperscript{(18)} In this study, the addition of 80 nmol TTA to pure supercritical CO\textsubscript{2} increased extraction efficiencies of uranyl and thorium ions from water at 38\% and 70\%, respectively. The synergistic effect on extraction of each ion by using TBP and TTA mixed with pure supercritical CO\textsubscript{2} was investigated. Extraction efficiencies of ions increased to 70\% and 87\%, respectively. Addition of 5\% methanol as a modifier and TTA as a ligand to the extraction fluid increased extraction efficiencies of both ions to greater than 85\%. Similar results were reported in the same paper\textsuperscript{(18)} for the extraction of Th(IV) and U(VI) spiked onto cellulose-based filter paper. The percentage recovery was less than 70\% using pure CO\textsubscript{2}, but greater than 95\% when 5\% methanol-modified CO\textsubscript{2} was used. It was concluded that the extraction efficiency of both lanthanides and actinides depends on the structure of the ligand, following the order: TTA $\approx$ FOD $>$ HFA $>$ TAA $>$ acetylacetone (AA). They also evaluated the synergistic effect of TBP (12) for the extraction of lanthanides and actinides using both pure and modified supercritical CO\textsubscript{2} from solid matrices. Significant increases in the extraction efficiency of lanthanides and actinides from sand and filter paper (>90\%) were observed when an equimolar amount of TBP and ligand (HFA, TTA, or FOD) were added to the supercritical CO\textsubscript{2}. However, the extraction efficiency of the same lanthanides and actinides from the same matrices using supercritical CO\textsubscript{2} saturated with only ligand or TBP was not greater than 65\%.

A similar study was reported by Laintz and Tachikawa\textsuperscript{(25)} investigating the synergistic effect of 10, 20, and 30\% TBP-modified CO\textsubscript{2} saturated with TTA for the extraction of Sm\textsuperscript{3+}, Eu\textsuperscript{3+}, Gd\textsuperscript{3+}, Dy\textsuperscript{3+}, La\textsuperscript{3+}, Ce\textsuperscript{3+}, Yb\textsuperscript{3+}, and Lu\textsuperscript{3+} from an aqueous environment. Quantitative extraction of Sm\textsuperscript{3+}, Eu\textsuperscript{3+}, Gd\textsuperscript{3+}, and Dy\textsuperscript{3+} (>90\%) was achieved using 30\% TBP-modified CO\textsubscript{2} saturated with TTA while recovery of La\textsuperscript{3+}, Ce\textsuperscript{3+}, Yb\textsuperscript{3+}, and Lu\textsuperscript{3+} using the same extraction conditions was less than 70\%. Extraction of the same lanthanide ions from acidic solution (6 M HNO\textsubscript{3}, 3 M LiNO\textsubscript{3}) using 30\% TBP-modified CO\textsubscript{2} yielded extraction efficiencies of greater than 85\% for Sm\textsuperscript{3+}, Eu\textsuperscript{3+}, Gd\textsuperscript{3+}, and Dy\textsuperscript{3+}, while less than 70\% recovery of La\textsuperscript{3+}, Ce\textsuperscript{3+}, Yb\textsuperscript{3+}, and Lu\textsuperscript{3+} was obtained. The log of the SFE distribution coefficient was plotted as a function of percent TBP in the extraction fluid. The slope of the line for Sm\textsuperscript{3+}, Gd\textsuperscript{3+}, Eu\textsuperscript{3+}, and Dy\textsuperscript{3+} suggested that not only was TBP forming a 3:1 adduct with Ln(NO\textsubscript{3})\textsubscript{3} during extraction but it was also forming a 3:1 adduct with Ln(TTA)\textsubscript{3} during the extraction.

Later, Lin et al.\textsuperscript{(12)} studied the extraction of uranium (UO\textsubscript{2}\textsuperscript{2+}) and thorium (Th\textsuperscript{4+}) from nitric acid solutions using different organophosphorus reagents (i.e. TBP (12), TBPO (13), TOPO (14), and TPPO (15)). In all extractions, supercritical CO\textsubscript{2} was saturated by passing through a cell filled with an organophosphorus compound. Then the saturated CO\textsubscript{2} with organophosphorus compound was bubbled through the solution in the extraction vessel. Results showed that extraction efficiencies of both UO\textsubscript{2}\textsuperscript{2+} and Th\textsuperscript{4+} using TBP are directly dependent on the concentration of nitric acid solution. Extraction efficiencies of both ions decreased from 91\% for UO\textsubscript{2}\textsuperscript{2+} and 80\% for Th\textsuperscript{4+} in 6 M nitric acid solution to 12\% for UO\textsubscript{2}\textsuperscript{2+} and 20\% for Th\textsuperscript{4+} in 0.1 M nitric acid solution. Addition of LiNO\textsubscript{3} to the 6 M nitric acid solution increased extraction efficiencies of both ions to 98\% and 93\%, respectively. Extraction efficiencies of both UO\textsubscript{2}\textsuperscript{2+} and Th\textsuperscript{4+} using supercritical CO\textsubscript{2} modified with TBP were greater than 90\% regardless of the concentration of nitric acid solution (6 M, 1 M, or 0.1 M).

Meguro et al.\textsuperscript{(26)} developed the SFE method for the efficient separation of U(VI) from nitric acid solution by means of the dynamic extraction procedure using a supercritical CO\textsubscript{2}–TBP mixture and demonstrated a potential of SFE in the application to the reprocessing of spent nuclear fuels. More recently\textsuperscript{(27)} they established an equation whereby they were able to measure the distribution ratio of U(VI) from nitric acid solution into supercritical CO\textsubscript{2} containing TBP. The validity of the equation was examined by the measurement of the distribution ratio of the U(VI) as well as nitric acid under a wide range of pressures and temperatures. A simple linear relationship between distribution ratio, D\textsubscript{u}, of U(VI) and density, $\rho$, of CO\textsubscript{2} was derived: $\log D_u = \alpha \log \rho + A + B$, in which $\alpha$ is a proportional constant implying the solvation characteristic of the solute in supercritical CO\textsubscript{2}, $A$ is a pressure-independent constant, and $B$ is a variable determined by the distribution equilibrium of nitric acid. This equation would allow the user to enhance
the extraction selectivity of different metal ions. The \( \log D_0 \) vs \( \log \rho \) plots of metals of different kinds exhibited different characteristics.

### 3.5 Supercritical Fluid Extraction of Organometallic Compounds

In addition to these main classes of ligands, several other studies have been performed on other inorganic species. Different research groups have focused on extraction of organometallic compounds.

Wai et al.\(^6\) reported the extraction efficiency of spiked dimethylmercury and dimethylmercury onto filter paper. An extraction efficiency of greater than 99% was reported for both compounds using pure CO\(_2\) when filter paper was spiked with 10 \( \mu \)L of water. Ashraf-Khorasani and Taylor\(^7\) reported the extraction efficiencies of the same compounds from different matrices using both pure and methanol-modified CO\(_2\). Their results showed that dimethylmercury can be extracted with an extraction efficiency of greater than 90% from all matrices. However, results for the extraction efficiency of methyl mercury chloride showed that extraction was not only dependent on extraction conditions, but also dependent on the extraction environment and matrix.

Triorganotin compounds have been used for several years in agricultural science, (1) as a biocide to combat fungal growth, (2) in wood preservative formulations to reduce fungal rot, and (3) in marine plants as an antifoulant against barnacles.\(^28\) Diorganotins have routinely been used as heat and light stabilizers in the polymer and food-packing industries.\(^29\) Oudsema and Poole\(^30,31\) studied coupled on-line SFE and supercritical fluid chromatography (SFC) of organotin compounds using 0.3% formic acid-modified supercritical CO\(_2\). Separation of 12 organotin compounds was obtained using a Deltabond methyl column using 0.3% formic acid-modified CO\(_2\). In another experiment, on-line SFE/SFC was used to extract and separate different organotin compounds from marine paint and spiked into a potato or almond matrix. This study was focused mainly on SFC rather than SFE.

Lin et al.\(^32\) studied extraction of six tetraalkyltin and seven additional ionic organotin compounds from spiked topsoil using both pure and 5% methanol-modified CO\(_2\). All tetraalkyltin compounds were extracted from topsoil with recoveries of 90–110% using either fluid at 100 atm and 40 °C. However, recoveries of ionic organotin compounds ranged from 70–90% when Na(DDC) was added to the sample matrix in order to neutralize the change. The addition of 5% methanol as a modifier did not increase extraction efficiencies of ionic organotin compounds. Later, the same group extended their study to extract different ionic organotin compounds from clay and sediments. All soil and sediment samples were treated with diethylammonium DDC prior to extraction. Extractions were performed using both pure and 5% methanol-modified CO\(_2\). Results showed that most dialkytin, trialkyltin, and tetraalkyltin compounds can be quantitatively extracted from most of the matrices, while the percentage recovery of monoalkyltin compounds from all matrices was less than 20%.\(^33\)

Alzaga and Bayona\(^34\) and Cai and Bayona\(^35\) studied SFE of butyl-, phenyl- and cyclohexyltin compounds from aqueous matrices using C\(_{18}\) solid-phase extraction (SPE) discs. The analytes were first concentrated via SPE discs. Next, the organotin compounds that were trapped on the SPE disc were derivatized via Grignard ethylation followed by SFE at 100 atm. Extraction efficiencies of both di- and tributyltin were above 90%, while SFE recovery of monobutyltin was less than 70%.

An extraction efficiency of greater than 80% was obtained for tributyltin from both spiked and certified reference material (CRM) sediment using 347 atm, 60 °C and 20% methanol-modified CO\(_2\).\(^36\) The same group also studied in situ derivatization of butyltin and phenyltin from sediment using hexamagnesium bromide as a derivatizing agent and supercritical CO\(_2\) as an extraction fluid. Once again, the recovery of monobutyltin was less than 20%, while recovery of di- and tributyltin was greater than 80%. Recoveries of monophenyltin, diphenyltin and triphenyltin were 40, 106, and 114%, respectively.\(^37\)

Chau et al.\(^38\) compared extraction efficiencies of butyltin spiked in sediment and a CRM. Their results showed that up to 60% of monobutyltin could be extracted from spiked sediment, while the same analyte from the CRM using pure CO\(_2\) was not detected in the extract. Extraction of the same analyte from the CRM using Na(DDC)-modified CO\(_2\) increased the extraction efficiency of monobutyltin to 148%. The extraction efficiencies of di- and tributyltin from the CRM using Na(DDC)-modified CO\(_2\) were 79 and 85%, respectively.

SFE of alkyltin and alkyllead from solid samples (e.g. soil and polyvinyl chloride (PVC)) using both supercritical and subcritical chlorodifluoromethane was investigated.\(^39\) Quantitative recoveries of triethyllead and triethyltin were obtained, while low recoveries of trimethyltin and trimethyllead were obtained. Addition of Na(DDC) as a complexing agent to the extraction vessel increased extraction efficiencies of the two trimethylmetallic compounds to above 89%. They also demonstrated that the addition of Na(DDC) decreased extraction time by half. In addition, the extraction efficiencies of alkyltin and alkyllead compounds were improved using subcritical chlorofluoromethane instead of supercritical chlorodifluoromethane. A higher extraction efficiency of dibutyltin stabilizer from PVC plastic was
also obtained via subcritical chlorofluoromethane than dichloromethane liquid solvent extraction.

Johansson et al.\(^4\) extracted ionic alkyllead from both sediment and urban dust using modified supercritical \(\text{CO}_2\). They used different modifiers (methanol, water, and acetone) to optimize extraction efficiencies. Methanol provided the most favorable recoveries. At the optimum extraction conditions (\(80^\circ\text{C}, 446\ \text{atm}\), and 10% methanol added to the cell) recovery of trimethyllead, triethyllead, and diethyllead was 96, 106, and 80%, respectively.

Recently, Wenclawiak and Krak\(^4\) measured the extraction efficiencies of dimethylarsenic acid (DMA) \(^{(21)}\) and monomethylarsenic acid (MMA) \(^{(22)}\) from a solid sample using supercritical \(\text{CO}_2\). The DMA and MMA were derivatized under supercritical \(\text{CO}_2\) conditions using thioglycolic acid methylester (TGM) \(^{(23)}\). After 10 min of static extraction, the valve between the restrictor and extraction vessel was opened and the derivatized analytes were collected in a solvent. Extraction efficiencies of both DMA and MMA were greater than 90% at 400 atm. Temperature did not affect the extraction efficiencies of the derivatized analytes.

\]

**4 CONCLUSION**

Direct extraction of metal ions and preformed metal chelates via SFE from many matrices has been accomplished. Different ligands such as \(\beta\)-diketones, dithiocarbamates, crown ethers, and organophosphorus reagents can be utilized for extraction of metal ions. Results from different studies have demonstrated that fluorinated ligands afford higher metal complex solubility in supercritical \(\text{CO}_2\), which makes them more effective for extraction of metal ions. In order to obtain sufficient extraction not only should solubility be considered but also the stability of the complex. In the past few years several different review papers regarding both solubility and extraction behavior of inorganic and organometallic compounds in supercritical \(\text{CO}_2\) have been published.\(^{42–44}\) SFE of inorganic species is a growing field and one that offers a promising future.

Supercritical fluids (SFs) possess several physical properties that make them attractive substitutes for conventional liquid solvents in analytical-scale extractions. Molecular diffusivities of SFs are typically a factor of 10 greater ($10^{-4}$ vs $10^{-5}$ cm$^2$ s$^{-1}$) and their viscosities are a factor of 10 lower ($10^{-4}$ vs $10^{-3}$ Ns m$^{-2}$) than liquid solvents. These properties improve the rate of mass transfer of a solute from the matrix surface to the bulk extractions fluid—a transfer believed to be the rate-limiting step of most extractions. Under optimized conditions, the improvements in mass transfer can enable a supercritical fluid extraction (SFE) to be completed in less than 1 h compared to ≥12 h for extractions involving conventional solvent techniques. The typical SFE also generates little solvent waste, compared to traditional extraction methods, but limitations have also emerged with respect to the efficiency of SFE as related to the sample composition (matrix effect). This review will discuss the progress made over the last 20 years in SFE as an alternative technique to liquid solvent extractions of environmental samples for the subsequent measurement of organic constituents.

1 INTRODUCTION

Over the last 25 years, the field of environmental analytical chemistry has gleaned valuable information regarding the levels of global and regional contamination. In the process, analysts have generated significant quantities of potentially hazardous waste, particularly during the extraction of samples. Sample extraction, although generally regarded as less technically demanding than the modern separation and detection techniques, is certainly one of the most important parts of an analytical scheme, and if not chosen carefully, can doom an environmental analysis to failure. An ideal extraction technique should be fast, simple, and cheap. It should quantitatively extract the species of interest while minimizing decomposition, subsequent sample clean-up, and solvent waste. The Soxhlet extraction method, typically used by most environmental analysts, has not changed significantly in nearly 100 years and generally does not fulfill most of the requirements of an ideal extraction method. For example, Soxhlet extraction generates hundreds of milliliters of waste solvent per sample, typically takes 12–48 h to complete, and generally produces an extract that, although quantitative for most analytes associated with the sample (depending on the solvent used), requires clean-up prior to analysis. The cost to dispose of contaminated solvent waste in a responsible manner is usually even greater than the considerable expense of pure solvents employed for extractions of environmental samples. The time required for the extraction and subsequent clean-up, the expense of the pure solvents needed for the extractions, and the expense of disposal of large volumes of waste solvent, combine to make Soxhlet extraction a very expensive sample extraction technique indeed. These considerations have thus motivated research in minimizing the time and considerable waste generated during the conventional liquid solvent extraction of environmental samples (e.g. soil, sediment, solid waste, combustion material, air particulate matter).

There have been a number of reviews discussing the role of SFE in environmental analysis since this was initially believed to be the most important role of the technique. This review will discuss the progress made over the last 20 years in SFE as an alternative technique to liquid solvent extractions of environmental samples for the subsequent measurement of organic constituents.

2 THEORY AND INSTRUMENTATION

2.1 What is a Supercritical Fluid?

The simplest way to define an SF is to refer to the phase diagram for the specific substance. As an example, a phase
Supercritical CO₂ is not a universal solvent because its reactivity, nonflammability, and low cost for high purity. Its relatively low critical temperature and pressure, low activity, nonflammability, and low cost for high purity. Supercritical CO₂ is not a universal solvent because its solvent strength under the normal range of pressures (8100–61 000 kPa) allows it to solubilize mainly nonpolar solutes extracting at higher temperatures (50 °C) and nonpolar solutes extracting at higher temperatures (250 °C). These citations document the relatively few successes in selectively extracting specific species from complicated matrices. The majority of work in SFE

Figure 1 CO₂ phase boundary.

2.2 Thermodynamics and Kinetics of Supercritical Fluid Extraction

SFs possess several physical properties that make them attractive substitutes for conventional liquid solvents in analytical-scale extractions. Molecular diffusivities of SFs are typically a factor of 10 greater (10⁻⁴ vs 10⁻⁵ cm² s⁻¹) and their viscosities are a factor of 10 lower (10⁻⁴ vs 10⁻³ N s m⁻²) than liquid solvents.¹ These properties improve the rate of mass transfer of a solute from the matrix surface to the bulk extraction fluid—a transfer believed to be the rate-limiting step of most extractions. Under optimized conditions, the improvements in mass transfer can enable an SFE to be completed in less than 1 h compared to more than 12 h for extractions involving conventional solvent techniques.

Referring to the importance of mass transfer in extractions (see above), the ability of a SF to solubilize a specific analyte or class of analytes, at a given set of conditions, does not necessarily guarantee that SFE will extract all of the species of interest associated with a sample. Competition between the matrix sites and the SF for the analyte is probably a more important consideration in selecting a specific SF or solvent-modified SF for an extraction experiment.¹,²,⁶ However, if the analytes are not appreciably soluble in the SF, as demonstrated by spiking experiments on an inert substrate, then it is unlikely that quantitative SFE is possible with that specific set of analytes, sample matrix, and fluid. The solvating strength of SFs can approach those of liquids but only at very high pressures, since this parameter is directly related to fluid density. However, for volatile species, increasing the temperature of extraction can have a greater effect on extraction efficiencies than increasing the pressure.⁹,¹⁰ Since the solvating power of an SF can be varied by pressure, some have suggested that an SF could be made selective for a specific compound class by optimizing the pressure and temperature of the extraction.⁵,¹¹–¹⁴ However, King stated that unless the classes of analytes sought by an analyst differed significantly in their physical properties, selective extraction of the two chemical classes by SFE would be unlikely. The work described by another group employed sub- and supercritical water for selective chemical class extractions from environmental solids. Operating at constant pressure, with the knowledge that water’s dielectric constant decreases significantly with increasing temperature, they observed chemical class fractionation during SFE of environmental solids at different temperatures, with polar species extracting at lower temperatures (50 °C) and nonpolar solutes extracting at higher temperatures (250 °C). These citations document the relatively few successes in selectively extracting specific species from complicated matrices. The majority of work in SFE
has attempted to extract as much of specific analytes as that extracted by conventional liquid-based methods (e.g. Soxhlet), and has usually required temperature and pressure conditions not conducive to selective extractions.

A model proposed by Pawliszyn\(^{17}\) predicts that if conditions can be optimized to ensure no retention of the analyte by the matrix, complete extraction of the analyte can be performed by passing two void volumes of the SF through the extraction vessel. He discussed in detail how, for environmental solids, the rate of mass transport of the analyte from the matrix surface to the bulk fluid (desorption and diffusion rate-limiting processes) increases as the extraction temperature increases. An interesting requirement of the model is that the extraction fluid must be soluble in the organic layer presumed to coat most environmental solids, in order for the solute to be extracted into the bulk fluid. Perhaps a more realistic scenario would be that for extraction to take place, some or most of this organic layer would need to be stripped from the particle to expose the solute to the extraction fluid. This would make any selective extraction of an analyte sorbed to the surface of a particle (or pore of a particle) difficult, as the co-extracted organic material would certainly make the extract more complex.

Another model was developed by Bartle et al.,\(^{18}\) which theorized the extraction kinetics of an idealized sample consisting of spherical particles of similar size in which the analytes of interest are uniformly distributed. Two other assumptions of this model were that the flow of SF past the sample was fast enough to prevent a significant concentration of the analyte from accumulating in the fluid and that the analytes move through the matrix by diffusion. Plotting the kinetic extractions profiles \([\ln(m/m_0)]\) vs time, where \(m\) is the mass of the analyte remaining with the sample after time \(t\) and \(m_0\) is the mass of the analyte associated with the sample at time zero, of both ideal and real samples, they observed an exponential decline in \(m\), followed by subsequent linear decay over a long period of time. The \(m_0\) or total mass of analyte associated with the sample could then be extrapolated from extracted analyte masses obtained at three different times, one during the exponential decay period and two taken at equal time periods during the linear decay of the mass of analyte associated with the sample.

Clifford et al.\(^{19}\) refined the model proposed by Bartle et al.\(^{18}\) which considered the single rate-limiting step of an SFE to be diffusion of the solute from interior pores to the edge of the sample particle. Clifford et al.\(^{19}\) proposed that reversible desorption of the solute from matrix sites and removal of the solute from the edge of the sample particle into the bulk fluid should also be considered as rate-determining processes in SFE. This was the first SFE model to acknowledge the importance of solute–matrix interactions in directly affecting the efficacy of SFE with some environmental samples. This matrix effect is probably one of the most prominent limitations of SFE, as workers have observed significant differences in SFE extraction efficiencies of the same solutes from similar samples extracted under identical conditions.\(^{20}\) Specific examples will be discussed below.

### 2.3 Supercritical Fluid Extraction Instrumentation

Instrumentation requirements for SFE range from simple to complex, depending mostly on the level of automation required for the application. For a simple manual instrument set-up for SFE, as shown in Figure 2, one needs a fluid pump capable of relatively high pressures (20–50 MPa), a sample vessel and associated plumbing (tubing) rated at significantly above the method operating pressures, a valve or flow restrictor, and a collection device, using either a liquid- or solid-phase medium. Commercially available SFE instrumentation typically consists of high-pressure reciprocating or syringe pumps. The reciprocating pumps are typically modified high-pressure liquid chromatographic pumps that allow continuous extraction, whereas syringe pumps are typically filled and pressurized prior to extracting. Syringe pumps can typically operate at higher pressures – as high as 68.9 MPa – than reciprocating pumps, and thus allow for investigations at higher-pressure regimes. Reciprocating pumps offer the advantage of larger extraction volumes than syringe pumps, since the limiting volume for the reciprocating pump would be that of the fluid supply tank. Automated commercial instruments are available for each of these pump systems.

Solid samples are typically packed into high-pressure cylindrical vessels and contained between frits and fittings. One manufacturer’s instrument extracts the sample cartridge in a chamber whereby the inside and outside surfaces of the extraction vessel are held at the same pressure, negating any need for thick and expensive metal extraction vessels. Most researchers in SFE recommend minimizing dead volume in the sample extraction vessel by adding inert material to the cell after the sample.\(^{6}\) This maximizes contact between the sample and extracting fluid.

The simplest collection method involves immersing the flow restrictor, employed to maintain the sample vessel at

![Figure 2 SFE apparatus for manual operation.](image-url)
supercritical pressures, in a suitable solvent and allowing the extract to dissolve in the solvent as the CO₂ decompresses. The cooling (Joule–Thompson cooling) resulting from the expansion of the CO₂ can improve collection efficiencies of volatile compounds as well as minimizing the decomposition of thermally labile species. Mulcahey et al. discussed potential problems that may arise during collection of an SFE in liquid solvent, including plugging of the restrictor by ice and losses of analytes as aerosols during the decompression of the extraction fluid. They evaluated the use of solid-phase traps for collection of species of different polarities, testing all the different traps for collection of polychlorinated biphenyls (PCBs) extracted by SFE from river sediment. Thompson et al. investigated the effectiveness of nine solvent collection systems for a test mixture consisting of solutes with different polarities. They found that multicomponent solvent mixtures were necessary for quantitative collection of all of the analytes in the test mixture. Two negative aspects of collecting on solid-phase traps are that the researcher must choose both the appropriate packing material for the traps as well as the type and volume of wash solvent. Miller et al. investigated the collection of aliphatic and aromatic hydrocarbons, and PCBs after static SFE. The extracts were collected without a flow restrictor after rapid depressurization into an empty vial, with good recoveries (>90%) obtained.

Automation has probably necessitated some of the more innovative developments in SFE instrumentation, and most systems can process from 8 to 24 samples. These systems typically include a variable-orifice restrictor that is controlled through feedback to the pumps. As a variable-orifice restrictor begins to plug during an extraction and the flow rate lessens, the orifice increases in size, causing expulsion of the plugging material, and the flow rate returns to the set-point. Simple linear restrictors, although inexpensive and easy to obtain, are prone to plugging and are generally not suitable for use in an automated instrument. Automated instruments, in turn, are the most appropriate for method development because multiple extracts can be generated from the same sample by methods using different extraction parameters (e.g. pressure, temperature, static and dynamic extraction times, fluid volume, fluid flow rate). Most automated SFE instruments will also allow access to sample logs, in which specific extraction parameters are recorded for each extracted sample.

3 SUPERCritical FLUID EXTRACTION OF ENVIRONMENTAL SAMPLES

One can classify environmental samples in three general ways. The first and most effectively extracted by SFE would include those samples whose particle surfaces are coated with the contaminating material, such as a fuel, waste oil, or pesticide formulation. In these cases and as long as the fluid employed can solvate the analytes of interest, SFE can be an effective alternative extraction technique to conventional solvent methods. The second sample type has a lower level of contamination and the species are strongly sorbed to surfaces of pores deep within the sample matrix. This sample type is much more difficult to extract by SFE, because, as described in model representations above, the fluid must overcome the interactions between the analyte and pore surface for the analyte to partition into the pore fluid and then diffuse into the bulk fluid before exiting the extraction vessel. This type of sample may also have experienced some aging and weathering, such that the external surfaces of the particle may be quite free of contamination and the bulk of the contaminating species are sequestered in the pores of the particles. The third type of sample includes both pore- and surface-associated analytes with a virtual continuum of relative proportions of each. Generally, the efficacy of SFE with respect to these sample matrices will be proportional to the relative amounts of analyte sorbed to the external surface of the sample particle (easy-to-extract analytes) compared to those deep within the pores (difficult-to-extract analytes) of the sample matrix. Other specific sample characteristics that may have direct effects on the efficiency of SFE include percentage of carbon, clay content, specific surface area, acidity, and pore size distribution.

Most of the environmental SFE applications published in the last 15 years, some examples of which are noted below, have involved the extraction and measurement of aliphatic hydrocarbons, aromatic hydrocarbons, PCBs, pesticides and herbicides. The United States Environmental Protection Agency (USEPA) has proposed SFE methods for extraction of total recoverable petroleum hydrocarbons (EPA method 3560), polycyclic aromatic hydrocarbons (PAHs, EPA method 3561), and PCBs and organochlorine pesticides (EPA method 3562), but these methods have yet to be approved.

Burford et al. developed an on-line SFE/gas chromatography (GC) method for determining gasoline and diesel fuel organics from environmental samples, observing comparable recoveries for all the fuel hydrocarbons compared to a sonication method with dichloromethane as the solvent, except for those of gasoline where the SFE-based method yielded higher recoveries than the conventional method. Higher recoveries observed for gasoline-contaminated samples were attributed to more efficient collection of the more volatile hydrocarbons by the SFE method. Similar work was also performed using an off-line method during which
fuel-contaminated soil samples were processed by an SFE method (40 MPa CO₂ at 150°C for 30 min) and a Soxhlet method using Freon-113 (1,1,2-trichloro-1,2,2-trifluoroethane) followed by analysis by both GC with flame ionization detection and infrared (IR) spectrophotometry (absorption at 2930 cm⁻¹). The SFE and Soxhlet extractions gave comparable results for the fuel-spill soils except for the gasoline- and kerosene-contaminated samples where the SFE method yielded higher recoveries than the solvent-based technique—similarly to results generated using the on-line method. Eckert-Tilotta et al. also discussed the important differences between real-world spill samples where the contaminants can diffuse into the sample matrix, making them difficult to extract, and spiked samples, where the analytes are generally on the surface of the sample, and are easier to extract. Lopez-Avila et al. used SFE to extract petroleum hydrocarbons from soil samples, processing extracts through silica gel to remove polar species and determining the total fuel hydrocarbons by IR spectrophotometry. The results of this nonspecific quantitative method were comparable to a traditional Soxhlet extraction method using Freon-113 as the solvent. An interlaboratory study was performed later that compared the accuracy and precision of the SFE-based methods for extracting petroleum hydrocarbons from soils. Mean recoveries for the SFE extraction method and the two types of IR instruments employed for the study ranged from 75.9 to 107% for three certified reference soils. For a clay soil spiked with petroleum hydrocarbons and containing 30% water, recoveries from the different laboratories were <38%, suggesting the need for drying agents for wet samples.

There have been a number of reports discussing the results of SFE of natural matrix samples for the subsequent measurement of PAHs. Schantz and Chesler reported good recoveries of PAHs from Standard Reference Material ((SRM), available from the National Institute of Standards and Technology (NIST)) SRM 1941 (Urban Dust/Organics) using supercritical CO₂ for 4 h extractions. Hawthorne et al. have used SRMs for more than 10 years in validating both off-line and on-line SFE approaches. They found that CO₂ and N₂O alone are not able to completely extract PAHs from the urban dust (SRM 1649) and sediment (SRM 1941) SRMs. They also reported that methanol-modified CO₂ and N₂O provided better PAH recoveries than the neat fluids, but the residual methanol created some problems with trapping and analysis. Lopez-Avila et al. used a marine sediment Certified Reference Material (CRM) from the National Research Council of Canada and a PAH-contaminated soil to evaluate SFE experimental conditions. They found that extraction recoveries of PAHs from both materials were poor when neat CO₂ was used as the fluid, and somewhat better, though generally less than quantitative (most recoveries ≤70% of Soxhlet extraction results), when methanol-modified CO₂ was employed as the fluid. During SFE of SRM 1941 (Organics in Marine Sediment), Pyle and Setty observed recoveries of ≤50% for most of the PAHs measured using CO₂ as the extraction fluid. Porter et al. described off-line SFEs of SRMs 1941 and 1974 (Organics in Muscle Tissue) using 10% methane chloride-modified CO₂ as the fluid. They reported good extraction recoveries compared with certified concentrations for all of the PAHs measured, and were the first group to report SFE results for the frozen mussel tissue reference material (SRM 1974).

The refrigerant chlorodifluoromethane (R₂₂) has been employed for use in SFE of environmental materials (e.g. air particulate matter, waste sludge, diesel particulate matter). Hawthorne et al. found that R₂₂ provided faster extraction kinetics and overall better recoveries of PCBs from SRM 1939 [Polychlorinated Biphenyls (Congeners) in River Sediment] than other fluids (CO₂ and N₂O) and modified fluids (methanol-modified CO₂). Paschke et al. reported that R₂₂ yielded excellent recoveries of PAHs from SRM 1650 (Diesel Particulate Matter) compared with NIST’s certified results. Two disadvantages of R₂₂ are its potential adverse impacts on stratospheric ozone and global warming.

High-temperature (200°C) CO₂ extractions of SRM 1649 (Urban Dust/Organics) have yielded significant enhancements in recoveries of PAHs compared with more moderate temperature extractions (50°C) at the same pressures. Yang et al. found that improved PAH recoveries by SFE at 200°C from environmental solids were observed for three different matrices (marine sediment, diesel soot, and air particulate matter). They also observed that addition of modifiers did not always improve PAH recoveries compared with pure CO₂ at the same temperatures. Perhaps the most significant conclusion reached by Yang et al. was that improvements in recoveries of PAHs affected by modifiers depended more on the interactions of the modifier with the matrix substrate than on the interactions between the modifier and the analyte (solubility). In this way, the modifier sorbs to the matrix sites, discouraging the readesorption of the analytes to the matrix sites, and thus facilitating analyte transport into the bulk fluid. It should be noted that for all of the temperature/modifier and sample matrix combinations investigated by Yang et al., recoveries of the highest molecular weight PAHs analyzed, indeno[1,2,3-cd]pyrene and benzo[ghi]perylene (both 276 m/z isomers), were usually ≤70% of certified results or those obtained by Soxhlet extraction. One group reported recoveries of phenanthrene, fluoranthene, and pyrene in
SRM 1649 (Urban Dust/Organics) from 150% to nearly 300% of the certified concentrations using different modifier–CO₂ combinations at a moderate temperature (80°C). Another worker performed the same extractions under the same conditions as Langenfeld et al. and observed good recoveries of the three PAHs (≥86% of certified concentrations) but not 1.5 to 3 times the certified recoveries as previously reported. (44) Benner applied SFE to four natural matrix SRMs using different fluids [CO₂ (neat and modified), chlorodifluoromethane, and 1,1,1,2-tetrafluoroethane], temperatures (60°C, 150°C, and 200°C), and added water. For two of the four sample matrices (SRMs 1649 and 1944), conditions were optimized to obtain recoveries similar to those achievable with Soxhlet extraction. For SRM 1941a (Organics in Marine Sediment) and SRM 1650 (Diesel Particulate) recoveries for benzo[ghi]perylene, the largest of the PAHs studied in this work, were at best ≤50% and ≤20%, respectively, of the certified concentrations. Meyer et al. attempted to extract PAHs from a soil with a high carbon content (a mass fraction of approximately 50% C) and found that 5% toluene-modified CO₂ at 140°C yielded similar concentrations of analytes to that of Soxhlet extraction (hexane/acetone). Another group suggested that SFE extracted significantly more PAHs from a highly contaminated sediment than Soxhlet extraction (dichloromethane) and somewhat more than that of microwave-assisted extraction (acetone or dichloromethane). Lee et al. optimized a CO₂-based SFE method for extracting 16 priority pollutants PAHs (naturally incurred) from sediments, using a mixture of water, methanol, and dichloromethane as modifiers, extracting at 120°C for 70 min. Friedrich et al. used triethylamine-modified CO₂ to demonstrate comparable recoveries of PAHs with respect to Soxhlet for a sewage sludge and sediment sample, though extraction times were as long as 2 h, compared with typical SFE extraction times of 30 min to 45 min.

Unlike PAHs, where there is a typical trend of lower recoveries with increasing molecular weight, the less-chlorinated PCB congeners (e.g. three substituted chlorines) are usually more difficult to extract by SFE than the more heavily chlorinated congeners (four to seven substituted chlorines). As an example of this extraction behavior, one group observed under optimized conditions that PCB 28 (2,4,4′-trichlorobiphenyl) was recovered at 63% of the Soxhlet extraction result from a river sediment (SRM 1939) and the tetra- through hepta-congeners were recovered at from 83% to 128% of the Soxhlet values, respectively (chlorodifluoromethane, 40.5 MPa, 100°C). Bowadt et al. performed SFE of PCBs from lyophilized fish tissue, achieving comparable recoveries of PCB congeners to those of the traditional extraction technique. The method included the use of coupled columns (SIL-8 and HT-5 phases), which improved congener separation compared with that of single column methods. Hale and Gaylor also performed SFE of lyophilized fish tissues for PCBs, observing results comparable to those achieved by conventional solvent extraction for a number of PCBs from a candidate fish tissue reference material. Hale and Gaylor found that by adding alumina to the collection vial, one eliminated the need for removal of lipids from the extracts. As part of a comparison of Soxhlet and SFE for extracting PCBs from an industrial soil, researchers found that SFE yielded comparable results to that of Soxhlet for 12 PCBs, quantifying the congeners by using the dual column system described above. Schantz et al. compared Soxhlet and SFE for their efficacy in extracting PCBs from two natural matrix sediment SRMs (SRM 1941a and SRM 1944) and a lyophilized mussel tissue SRM (SRM 2974). The SFE and Soxhlet results compared quite favorably for all three SRMs, suggesting that the SFE method should be considered as an alternative method for extracting PCBs from a variety of environmental samples.

Application of SFE to the extraction of pesticides and herbicides was logical, given the reactive nature of those classes of compounds and the relatively gentle extraction conditions typically used in SFE. McNally and Wheeler spiked soils, plant materials, and cell culture media with sulfonylurea herbicides, extracting with SF CO₂ and analyzing the extracts by SFC. Hopper and King built an SFE extractor that was designed to extract pesticides from a wide variety of foods. Recoveries of spiked pesticides were typically ≥90%, but recoveries of incurred pesticides appeared to be matrix-dependent. Lehota and Ibrahim developed an SFE method for extracting pentachloronitrobenzene pesticides from a variety of vegetables, with an average recovery reported as 90%. Izquierdo et al. found that SFE of soils and cereals spiked with carbamate pesticides resulted in recoveries, at best, of 6% for methiocarb to 80% for aminocarb. Another group compared SFE with liquid-vortex extraction ((LVE), acetonitrile–water–acetic acid) for their ability to extract four pesticides from soil, analyzing the extracts by enzyme immunoassay analysis (EIA) or GC. The SFE/EIA results for atrazine and alachlor were comparable to those obtained by LVE/GC. Lower recoveries were observed by SFE/EIA for simazine, compared with the LVE/GC method.

The majority of SFE environmental applications, a survey of which is described above, involve extraction and measurement of organic species. One group has employed SFE for the extraction of heavy metals and radionuclides after mobilization with a chelating agent and dissolution in supercritical CO₂. These
applications can be scaled-up to serve as techniques for mitigating environmental problems or for reprocessing nuclear waste.

In the last five years, pressurized fluid extraction (PFE), a method using conventional liquid solvents at elevated temperatures and pressures, has been introduced, offering the benefits of significant reductions in both time and solvent consumption compared with Soxhlet extraction. Richter et al. described results of PFE for both spiked and native analytes (PAHs and PCBs) from environmental samples and reference materials. Schantz et al. employed six natural matrix SRMs and two natural matrix CRMs for evaluating the effectiveness of PFE in extracting PAHs, PCBs, and chlorinated pesticides. They concluded that PFE yielded results comparable to Soxhlet extraction for all of the materials and analytes investigated and greater recoveries than Soxhlet extraction for the higher molecular weight PAHs from one of the SRMs (SRM 1650, Diesel Particulate Matter). This relatively new extraction technique has probably reduced efforts in developing SFE methods to replace existing Soxhlet extraction methods since PFE uses the same liquid solvents as Soxhlet and its extraction efficiencies have, thus far, been shown to be independent of the sample matrix – unlike SFE.

4 THE FUTURE OF SUPERCRITICAL FLUID EXTRACTION OF ENVIRONMENTAL SAMPLES

During the last 15 years there has been much progress made in the area of sample extraction for environmental analysis, driven mainly by concerns of extraction times and waste solvent. Initially, SFE was regarded as the panacea for sample extraction, but like all emerging techniques, its limitations in extraction efficiencies of specific chemical classes and sample types (matrices) began to emerge. Employing an SFE method as a replacement for an existing method must be done only after comparison with a traditional extraction method. After implementation, the SFE method should still be verified routinely by comparison with a solvent-based extraction technique using a standard material of known composition and homogeneity (e.g. CRMs), since subtle differences in the sample matrix can have detrimental effects on SFE recoveries.

Recent work describing the use of sub- and supercritical water as an extraction fluid have excited the SFE, environmental analysis, and environmental mitigation communities. By taking advantage of the significant changes in the dielectric constant of water with respect to temperature, this solvent is able to extract a wide range of chemical classes, and could conceivably be used on a large scale to clean up chemical waste sites contaminated with both organic and inorganic pollutants. On-line SFE applications have been shown to be some of the most sensitive methods for qualitative/quantitative analysis of very small samples (less than or equal to micrograms of sample material), and have not received the attention that they deserve from the environmental analytical community. Although on-line SFE would be subject to the same matrix effects as off-line methods, in sample-limited environmental applications the on-line technique may be the only way of obtaining chemical information (qualitative and/or quantitative) from a small sample.

The future of SFE in environmental analysis really depends on the willingness of researchers in the field to continue to investigate applications where SFE shows a clear benefit over conventional (Soxhlet and ultrasonic extraction) and new (PFE) liquid solvent-based methods. This future is not clear and may also depend on the amount of pressure regulatory agencies place on the environmental analytical community to further reduce solvent use in sample extractions.

Gas chromatography (GC) with quadrupole mass spectrometry (MS) is one of the most powerful and widely used analytical techniques. This technology combines the high resolving power of GC with the excellent sensitivity and chemical-structure-informing power of quadrupole MS. The combination of these two techniques provides both the selectivity and sensitivity needed for qualitative and quantitative analysis of organic analytes at trace levels in a wide variety of matrices.

This article provides an overview of the development and combination of these two technologies. Types of quadrupole mass spectrometers that are commonly coupled to gas chromatographs are discussed. Both electron ionization (EI) and chemical ionization (CI) are reviewed. Sample preparation methods are discussed for air, water, and solids. The different approaches employed for highly volatile and semi-volatile substances are presented. The use of chemical derivatives to improve sample response and various instrumental analysis considerations are also covered.

1 INTRODUCTION

When considering analytical informing power, cost-effectiveness, and extent of applications, gas chromatography (GC) with quadrupole mass spectrometry (MS) detection is arguably the most powerful analytical technique available today. It is one of the most commonly used techniques for the trace analysis of organic compounds in water. This article will give an overview of this technology and its applications to the analysis of trace organic compounds in water, soil, and air.

The combination of gas chromatography/mass spectrometry (GC/MS) provides the advantages of the high separation power of GC with chromatographic resolving powers of several hundred thousand theoretical plates per column, and the incredible sensitivity and qualitative selectivity of MS. GC is frequently coupled with selective detectors such as flame ionization, electron capture, flame photometry, etc. These combinations provide only the retention time and the selectivity of the detector as criteria for compound identification and quantitation. The use of a mass spectrometer as the GC detector provides the equivalent of hundreds of detectors in parallel – one at each mass-to-charge ratio measured. This additional dimension of mass-to-charge ratio, in conjunction with retention time, provides an even further increase in selectivity by the connectivity relationships between fragment ions from the same molecular species. Thus, GC/MS provides a selectivity of qualitative identification that is available from few analytical technologies. Further enhancements to selectivity and sensitivity also can be obtained by the use of different ionization techniques, e.g. chemical ionization (CI) or electron ionization (EI).

The importance of the mass spectrometer as a detector for GC can be gleaned from the biannual review of GC published in Analytical Chemistry. As observed by Arpino, a 1996 review of GC cited 1300 papers on GC, where 58% employed MS as the detector. In a more recent review in 1998 the percentage using MS detection was 26%. Since GC has been described as “the world’s most widely used analytical technique”, the number of analyses per year performed by GC/MS is truly large (possibly several hundred thousand). The quadrupole...
mass spectrometer and quadrupole ion trap mass spectrometer are the most common mass spectrometers used in conjunction with GC. According to the noted mass spectrometrists, Professor Fred W. McLafferty of Cornell University, “Certainly, the number of quadrupoles sold and in use far exceeds the total of all other types of mass spectrometers”. This article will review the history of the development of quadrupole mass spectrometers interfaced to gas chromatographs, and the sample preparation and application of quadrupole GC/MS for the analysis of trace organic compounds in water and other matrices.

2 HISTORY OF GAS CHROMATOGRAPHY/QUADRUPOLE MASS SPECTROMETRY

2.1 Invention of the Quadrupole Mass Spectrometer

The invention of the quadrupole mass spectrometer was conceived and executed first by Paul and Steinwedel in the early 1950s at the University of Bonn. Paul’s first efforts involved focusing an ion beam using a hexapolar magnetic field. In a subsequent collaboration with Steinwedel, they used a combination of a four-pole electrical field with a superimposed radiofrequency (RF) field to separate ions with different mass-to-charge ratios. This instrument was developed later into today’s linear quadrupole mass spectrometer and was patented in 1956. Paul shared the 1989 Nobel Prize in Physics with Dehmelt for his pioneering work on the development of quadrupole mass spectrometers.

The first commercial quadrupole mass spectrometer was built as a residual gas analyzer by Electronic Associates, Inc. in 1964. It was not until 1967 that Finnigan and others established Finnigan Instruments Corporation with the express purpose of constructing the first commercial quadrupole-based GC/MS instrument (Model 1015). The first instrument was delivered in 1968. Approximately 1 year later, Hewlett-Packard introduced its own quadrupole GC/MS instrument.

Paul and Dehmelt also developed the quadrupole ion trap in the 1950s. However, it remained something of a laboratory curiosity until the early 1980s when Stafford at FinniganMAT developed a scanning technique for the quadrupole ion trap, called the mass selective instability mode, which made the instrument much more analytically useful. In 1983, FinniganMAT introduced the first commercial gas chromatograph/quadrupole ion trap mass spectrometer. Subsequently, other manufacturers have produced quadrupole ion traps interfaced to gas chromatographs.

In 1976 the United States District Court mandated that the United States Environmental Protection Agency (USEPA) needed to analyze for 65 compounds in the nation’s wastewater. This list of compounds was subsequently named the “priority pollutants” and expanded to 129 compounds that included 114 organics: 25 pesticides and polychlorinated biphenyls (PCBs) and 89 other organics. This action led to the establishment of GC/MS as the mandated method for analysis of the environmental samples under the Clean Water Act Series 600 methods and the Solid Waste Manual SW-846 methods. The USEPA methods for volatile and semi-volatile organics in water (Methods 624 and 625, respectively) were promulgated in December 1979. The adoption by the USEPA of these standardized GC/MS methods using quadrupole mass spectrometers contributed greatly to a phenomenal growth in the use of quadrupole GC/MS. It is estimated that the worldwide market for mass spectrometers was $20–30 million per year in 1968, which was dominated by magnetic sector mass spectrometers. By 1994, the MS market had grown to $750 million per year, with quadrupoles accounting for more than 75% of the market.

2.2 Interfacing Gas Chromatographs to Quadrupole Mass Spectrometers

During the early 1950s, gas–liquid chromatography was being developed by James and Martin. Their first report on gas–liquid chromatography appeared in 1952, the same year that they received the Nobel Prize for the development of partition chromatography. The initial reports of a GC/MS interface were by Holmes and Morrel in 1957. The instrument that they used was a slow-scanning magnetic sector mass spectrometer, which severely limited its applicability. Gohlke and McLafferty at the Dow Chemical Company coupled a gas chromatograph to a very fast time-of-flight mass spectrometer in the mid-1950s. In their instrument, the effluent of the GC was split between the mass spectrometer and a thermal conductivity detector, and the flow to the mass spectrometer was controlled by an adjustable needle valve.

Because the first GC systems used packed columns with flow rates of tens of milliliters per minute, interfacing to a mass spectrometer generally required the use of devices to remove some of the carrier gas and enrich the sample. Otherwise, the carrier gas load on the mass spectrometer source would be too high. Four different approaches to GC/MS interfaces were commonly used: effusion through a fritted tube; diffusion through permeable membranes; diffusion using a jet separator; and a modification of this – the open-split interface. The fritted-glass-tube interface was introduced by Watson and Bieman in 1964. The carrier flow from the exit of the gas chromatograph entered the device through a glass constriction to reduce the pressure. The
flow was directed through a tube constructed from glass containing pores of approximately 1 µm in diameter. The outside of the tube was pumped with a mechanical rough pump. The carrier gas effused through the frit faster than the analytes. A constriction on the output to the mass spectrometer helped to control the gas pressure in the mass spectrometer. Enrichment factors (outlet concentration/inlet concentration) were about 50, with efficiencies of 25–40%.

Diffusion-based jet separators were introduced by Ryhage in 1964: he used two jet separators in series.\(^{(12)}\) The principle of operation depends upon the difference in momentum between the carrier gas and the analytes eluting from the GC column. In the more modern jet separator pictured in Figure 1, there are two small-diameter tubes that face each other, separated by a gap of less than 1 mm. The region surrounding the tubes is connected to a vacuum pump. Typical carrier gases, such as helium or hydrogen, are much lighter than most analytes eluting from the column and readily diffuse into the vacuum chamber. The analytes eluting from the column, however, are usually much heavier with much higher momenta, and therefore do not diffuse as readily into the vacuum. The gas flow out of the jet separator was thereby much enriched in the heavier components, and the total gas flow was reduced enough to make the gas load manageable in the mass spectrometer source. Enrichment factors were about 100, with efficiencies up to 60%.

In 1966, Llewellyn and Littlejohn\(^{(13)}\) introduced a membrane-based separator that depended on the permeation of the analyte through a membrane. The process depended on the solubility and diffusion rate of the analyte through the membrane that separated the outlet of the GC column from the inlet of the mass spectrometer. The membrane was an elastomer in which helium had a very low solubility. Enrichment factors as high as \(10^5\) were achieved, with efficiencies of 50%. However, one drawback of membrane interfaces is that they degrade the chromatographic resolution by adding to the extra-column band-broadening.

The use of capillary columns in GC enabled the direct coupling of the chromatographic column to the mass spectrometer source. The flow rates for capillary columns, usually of the order of 1 mL min\(^{-1}\), results in much lower gas loads on the mass spectrometer source. This factor, coupled with more efficient differential pumping of mass spectrometer sources, has allowed direct interfacing of the GC column to the MS source in modern GC/MS instruments. This difference means more efficient transfer of eluting peaks from the gas chromatograph to the mass spectrometer and less degradation of chromatographic resolution. Jet separators and open-split interfaces continue to be used in some applications.

### 2.3 Types of Quadrupole Mass Spectrometers Used for Gas Chromatography/Mass Spectrometry

Three types and configurations of quadrupoles are commonly used for GC/MS. The most common is the simple linear quadrupole mass filter. A combination of three linear quadrupoles connected in series is used less frequently due to cost and complexity, but has the significant advantage of performing tandem MS. The third type that is rapidly growing in popularity is the quadrupole ion trap, which can perform tandem MS without the expense of the triple quadrupole. Each of these instruments is discussed below.

A simple, linear quadrupole mass filter is presented in Figure 2. There are a number of excellent, detailed...
descriptions of the operation of quadrupoles,\textsuperscript{(8,14)} and only a brief overview will be given here. The quadrupole mass spectrometer is actually a mass-to-charge filter. True mass spectrometers disperse a beam of ions according to their \textit{m}/\textit{z} (e.g. in a magnetic sector instrument the ion beams are separated in space and emerge at different angles from the magnet). Similarly, a time-of-flight mass spectrometer separates the ion beam into different packets of ions that emerge from the analyzer at different times. The quadrupole mass spectrometer only passes a band of ions of a selected \textit{m}/\textit{z}, and all the other ions are lost to the surfaces of the analyzer. This difference is due to how the quadrupole operates.

In the quadrupole filter, diagonally opposing pairs of rods are electrically connected. The two pairs of rods are connected to opposite direct current (DC) voltages of the same magnitude but opposite polarities, and their RF voltages are shifted 180° out-of-phase with respect to each other. An ion entering the quadrupole from one end will travel in a zig-zag course toward the opposite end in synchrony with the RF field. For a particular value of the DC and RF voltages, the solutions to the differential equations are such that only a particular \textit{m}/\textit{z} ion will travel on a stable trajectory and traverse to the opposite end of the filter where the detector is located. All other ions will undergo unstable oscillations and either collide with the rods or exit the gaps between the rods to collide with the surfaces of the vacuum chamber – these ions will not traverse to the end of the filter. When an ion collides with a surface, it will be discharged and become a neutral molecule that will eventually be pumped away by the vacuum system. The DC and RF voltages and the RF govern the \textit{m}/\textit{z} ratio of the ions that the quadrupole will pass; therefore, the device acts as an \textit{m}/\textit{z} filter. Changing the magnitudes of the RF and DC voltages but keeping their ratio constant scans the \textit{m}/\textit{z} that the quadrupole filter will allow to pass. The frequency of the RF is also kept constant and is usually several hundred kilohertz (e.g. 700 kHz).

One of the features of the quadrupole mass filter is that it can be used as an ion-focusing device if the DC component is turned off. Thus, an RF-only quadrupole

---

\textbf{Figure 3} Triple quadrupole mass spectrometer scan modes: (a) product ion scan; (b) precursor ion scan; (c) neutral loss scan.
can be used to transmit ions with a broad range of \( m/z \) values and kinetic energies. Yost and Enke\(^{(15,16)}\) took advantage of this property to construct an ion collision chamber in their invention of the triple quadrupole mass spectrometer in 1979. In this device, quadrupoles one (Q1) and three (Q3) can be scanned in the usual manner using RF and DC voltages, and the middle quadrupole (Q2) is RF-only, which usually contains a collision gas such as argon at relatively high pressures (in the millitorr region). Ions exiting Q1 are activated by collisions with the argon in Q2. The kinetic energy of these collisions is converted into internal vibrational modes and the ions quickly dissociate into characteristic fragment ions that are analyzed in Q3. This ion activation/dissociation technique is commonly referred to as collision-induced dissociation (CID). The entire process of ion selection, CID, and product ion analysis is referred to as tandem MS and provides considerable qualitative structural information and improvements in signal-to-noise ratios for quantitative target compound analysis.

There are three scan modes that enable the triple quadrupole to be very useful for both qualitative and quantitative analysis (Figure 3). In a product ion scan (Figure 3a), ions are selected by their \( m/z \) in Q1, undergo CID in Q2, and are mass analyzed in Q3. This scan mode is particularly useful in providing structural information from the fragmentation pattern of species that do not readily fragment upon ionization in the mass spectrometer source. For example, CI frequently gives a prominent \((M + H)^+\) ion but very little structural information. A product ion scan can provide this information. In a precursor ion scan (Figure 3b), Q3 is set to pass only a particular \( m/z \). Q1 is scanned to provide information on what species fragment to give the species detected in Q3. An example of the application of this scan mode is in the analysis of the priority pollutant phthalate esters in the environment by Hunt et al.\(^{(17)}\) These authors performed methane CI on unseparated mixtures of phthalates in environmental sample extracts using a precursor ion scan of \( m/z \) 149, which is a characteristic fragment ion for these compounds. The presence of the phthalates in the sample was confirmed by the presence of the characteristic \((M + H)^+\) ions and fragment ions that give rise to \( m/z \) 149. In a neutral loss scan (Figure 3c), Q1 and Q3 are scanned at a constant \( m/z \) offset that represents the loss of a particular functional group (i.e. the system is set to detect only a particular chemical group that is lost upon CID). As an example, Hunt also found that all but one of a series of priority pollutant chlorinated hydrocarbons underwent the neutral loss of the \( \text{Cl}^+ \) radical and \( \text{HCl} \). Therefore, performing a neutral loss scan at 35 and 36 is a way of monitoring for the presence of chlorocarbons.

The third type of quadrupole used is the quadrupole ion trap. This device has the great advantage of being able to act as a mass spectrometer and as a device that can be used to store/isolate ions, collisionally activate a selected ion, trap the product ions and scan their \( m/z \) ratios. In essence, the ion trap acts as an “electric field test tube” and consists of three electrodes, shown separated (Figure 4\(^{(18)}\)) and assembled with electrical connections (Figure 5). Two of the electrodes are of hyperboloidal geometry and are called the end-cap electrodes. The end-cap electrodes have small holes in them that can be used to admit ions into the trap or used for the detection of ions ejected from the trap. The third electrode is in the shape of a ring with a hyperbolic cross-section on the inner surface of the ring. Thus, the quadrupole ion trap actually consists of only three electrodes, but in cross-section it looks similar to the end-view of the linear quadrupole mass filter and the equations that govern the motion of the ions are similar for the two devices. Thorough and excellent descriptions of the operation of the ion trap are given in a series of works by March et al.\(^{(18–20)}\) The popularity of the ion trap as a mass spectrometer for
separations has grown primarily because it is a relatively low-cost device and is capable of performing tandem MS. It is estimated that more than 4000 ion traps had been sold by 1997 at a total cost of $250 million.\(^{(18)}\)

3 IONIZATION METHODS

3.1 Electron Ionization

EI is the oldest and most widely used ionization technique in MS. It has its roots in the development of MS made by J.J. Thomson at the beginning of the 20th century. EI continues to dominate MS because it is the simplest ionization technique to implement. EI deposits enough excess energy in the molecular ion to cause at least partial fragmentation, and extensive libraries of EI mass spectra are readily available. One of the chief disadvantages of EI is that it requires the analyte to be present in the mass spectrometer source as a vapor and is therefore only applicable to molecules that are vaporizable and stable in the gas phase. The minimum vapor pressure required is about 1 \(\times\) 10\(^{-6}\) Torr. This disadvantage means that EI is not applicable to a wide range of organic compounds, e.g. salts (quaternary amines, carboxylates, etc.), nonionic hydrogen-bonded functional groups (carbohydrates, amino acids, oligonucleotides, etc.) and species of large molecular weight. In spite of these disadvantages, EI is still the most widely used ionization technique in MS because of the strong advantages listed above and because the range of compounds applicable to EI matches well with the wide variety of compounds used commercially. The molecular weights of these compounds primarily cover species below molecular weight 500.

All MS techniques require the formation of an isolated ion in the gas phase. In EI, the molecule to be ionized is heated to provide a pool of molecules in the vapor phase. The pool of gas-phase molecules can come from the effluent of a gas chromatograph, which makes EI an ideal match for GC. Ionization is accomplished by collision between an analyte molecule and an electron accelerated off a heated tungsten wire (the “filament”). The typical energy of the electrons used for EI is 70 eV, which is generated by a potential difference of 70 V between the filament and the body of the ion source. A diagram of this process is shown in Figure 6. Because the nuclei of atoms are extremely small compared to the electron cloud, the most probable collisions will occur between the 70-eV electron and an electron circling the molecule. This collision results in the ejection of an electron from the molecule and results in the formation of a molecular radical cation, \(M^{+*}\). This cation is accelerated out of the ion source by the negative potential on an extracting plate, by a potential on the entire source, or by a combination of these as illustrated in Figure 6. The EI process can be represented by Equation (1):

\[
M^0 + e^- (70\text{eV}) \rightarrow M^{+*} + 2e^- \tag{1}
\]

In addition to providing enough energy to ionize the molecule, internal energy is also deposited in the resulting radical cation. This internal energy can be as high as 350 kcal mol\(^{-1}\), which is enough energy to fragment even the strongest chemical bond. If the time required for fragmentation is longer than about 10\(^{-8}\) s, the \(M^{+*}\) ion will travel through the mass spectrometer and be measured at the \(m/z\) of the intact molecular ion. Usually, a portion of the \(M^{+*}\) molecules dissociates in the source of the mass spectrometer and is measured as fragment ions that can be used to characterize the chemical structure of \(M^{+*}\), because the fragmentations follow well-known rules. The resulting mass spectrum consists of ions that represent the molecular weight of the molecule as well as ions that characterize the chemical structure of the molecule. The EI mass spectrum, therefore, contains a wealth of information about the molecules entering the source of the mass spectrometer.

There are some disadvantages to EI. Only about 1 in 10 000 of the molecules present in the ion source are ionized by the EI process, making it an inefficient ionization process. In addition to this, many molecules do not give an ion that represents the intact molecule (called the molecular ion). Two examples of molecules that give weak or absent molecular ions are long-chain, branched hydrocarbons and alcohols (which usually fragment to lose water). For example, the percent abundances of the molecular ions for 3,3,5-trimethylheptane and \(n\)-decanol are 0.007% and 0.002%, respectively.\(^{(21)}\) This can lead to problems in identifying the compounds that produced

![Figure 6 Schematic diagram of an EI source.](image-url)
the mass spectrum, because many of the compounds of similar structure have very similar mass spectra.

### 3.2 Chemical Ionization

As an alternative to electron impact ionization, ionization of the sample can be produced using ionic reactions. This technique, called CI, uses a high pressure of a reagent gas (e.g. methane or ammonia) in the ionization source.\(^{(23)}\) The filament produces electrons as in EI (usually set to 100 eV), and these ionize the reagent gas. The reagent gas ions then react with the sample molecules to produce mainly molecular ions (through proton transfer for methane CI). The chemical reaction for the methane CI process is shown by Equations (2–4):

\[
\begin{align*}
\text{CH}_4 + e^- (100 \text{ eV}) & \rightarrow \text{CH}_4^+ + 2e^- \quad (2) \\
\text{CH}_4^+ + \text{CH}_4 & \rightarrow \text{CH}_5^+ + \text{CH}_3^- \quad (3) \\
\text{M} + \text{CH}_5^+ & \rightarrow \text{MH}^+ + \text{CH}_4 \quad (4)
\end{align*}
\]

The equilibrium of Equation (4) is governed primarily by the difference in proton affinity of the molecule M and methane. The proton affinity is shown by Equation (5):

\[
\text{M} + \text{H}^+ \rightarrow \text{MH}^+ \quad (5)
\]

The internal energy deposited in MH\(^+\) depends upon this difference in proton affinities. The extent of fragmentation of MH\(^+\) and the sensitivity to CI, therefore, can be controlled by choice of CI reagent ions and the difference in proton affinities with respect to the target analyte. The most common CI reagent ions are methane, isobutane, and ammonia, although many other reagent ions are used for specific applications. An example of the selectivity afforded by the judicious choice of CI reagent is illustrated by the use of ammonia as the CI reagent ion. Ammonia has a relatively high proton affinity (204 kcal mol\(^{-1}\)) so it will only donate its proton to molecules such as aromatic and aliphatic amines. Ammonia does not protonate alcohols, carboxylic acids, and hydrocarbons that do not contain the nitrogen moieties, because their proton affinities are lower than that of ammonia.

The major advantage of CI is that it produces primarily the protonated molecular ion, which makes it fairly easy to determine the molecular weight for the compound. Because EI usually produces a strong fragment ion spectrum and CI produces primarily the protonated molecular ion, these two techniques are complementary in nature. The major disadvantage of this technique is that it requires a better pumping system for the mass spectrometer due to the use of a high pressure of reagent gas, which leads to a higher cost for the instrumentation.

Another important type of CI is negative ion chemical ionization (NICI). In this technique, a reagent gas is used as in conventional CI, but it is used as a moderator for the electrons produced by the filament.\(^{(23)}\) These low-energy electrons are readily captured by many organic compounds, most notably halogenated compounds. The chemical reaction for the NICI process is shown by Equation (6):

\[
\text{M} + e^- \rightarrow \text{M}^- \quad (6)
\]

There are two major advantages of NICI. First, it is a highly selective technique, because only those compounds that contain a functional group with a high electron capture cross-section will be ionized by this technique. An application of this is the determination of PCBs in fish samples.\(^{(24)}\) The chlorinated biphenyls are efficiently ionized using NICI, whereas the lipids and oils in the fish matrix remain unionized, resulting in a very clean chromatogram. Secondly, NICI is a much more efficient process than either EI or positive ion CI. For compounds that contain multiple electronegative functional groups, the sensitivity can be several orders of magnitude greater under NICI mode than EI or CI.

### 4 SAMPLE PREPARATION AND ANALYSIS

This section presents the common methods used for the preparation of samples prior to analysis by GC/MS. For water samples, the desired detection limits are frequently less than can be achieved by direct injection of samples into the gas chromatograph. For example, the quantity detectable by a quadrupole mass spectrometer operated in EI mode is often of the order of several nanograms. Direct aqueous injection of 1 µL of water would lead to a concentration detection limit of several nanograms per microliter, i.e. in the parts-per-million range. A detection limit at the parts-per-million level is frequently several orders of magnitude too high for many environmental applications. Also, injection of water can be deleterious to many GC stationary phases over a long period of time. Hydrolysis of labile species can result from reaction with water on the hot surfaces of an injection port, and water is a poor choice of solvent for GC due to its high boiling point and polarity. For these reasons, samples are frequently subjected to extraction followed by concentration prior to analysis by GC/MS. Common preparation procedures are presented below for water, soil, and solid waste.

Sample preparation for GC/MS analysis is commonly divided into two techniques that depend upon the volatility of the species being analyzed. Volatile compounds are often considered as those species that have a boiling point below about 200°C; semi-volatiles are those...
species that are amenable to GC analysis and have boiling points above 200°C. The upper end of the temperature range accessible to GC includes species whose boiling points are less than approximately 350–400°C. There are, however, special GC columns designed for higher-temperature analyses. Fused-silica capillary columns coated with 5% diphenyl polysiloxane and 95% dimethyl polysiloxane are the most popular general-purpose columns. These columns have upper temperature limits of 350°C. Because of the temperature limitations mentioned above and the thermal stabilities of organic compounds, many classes of organic compounds are not amenable to GC/MS analysis. Various authors have estimated that GC is useful for only 20% of organic compounds. Examples of substances that cannot be analyzed by GC without prior derivatization include carbohydrates, proteins, fatty acids, salts, and other highly polar or high-molecular-weight species.

4.1 Sample Preparation for Volatile Organic Analysis

4.1.1 Sample Preparation for Volatiles in Water and Solid Samples

Volatile organic compounds typically analyzed by GC/MS include freons (chlorofluorocarbons), chlorinated solvents (such as methylene chloride and perchloroethylene), and aromatics (such as benzene and toluene). The analysis of these compounds in environmental samples presents the challenge of preventing losses between sampling and analysis. Samples need to be collected in scrupulously cleaned glass vials with Teflon® septum seals and stored at 4°C immediately after collection. For water samples, the vial should be filled gently to overflowing then sealed without a headspace gap between the top of the water and the septum. Soil, sediment, and waste samples need to be collected in preprepared glass screw-cap vials containing 5 mL of organic-free water, a clean magnetic stirring bar, and any preservative required (such as sodium bisulfite). Once the sample (typically 5 g) is placed into the vial and sealed with a Teflon® septum and cap, the vial is not opened until analysis.

Volatile organic compounds are most often prepared by purge-and-trap techniques, which are a type of dynamic headspace sampling. An inert gas, such as helium, is bubbled through an aqueous sample of 5–25 mL volume or a soil/sediment sample containing 5 mL of water for 11 min. The partitioning of the volatile organics between the aqueous phase and the vapor phase is governed by Henry’s law. Organic compounds of low aqueous solubilities are efficiently transferred to the gaseous stream, which is then passed through a metal tube containing a selection of various adsorbents to trap the organic compounds and remove them from the helium stream. The adsorbents commonly used include silica gel to remove water, charcoal to trap highly volatile species, and various polymers (such as Tenax®, a porous polymer resin based on 2,6-diphenylene-oxide) that trap the remaining compounds. After the purge cycle is completed, the trap is rapidly heated to 180°C or above (depending on the adsorbants used in the trap) and the analytes are back-flushed onto the GC column. Figure 7 shows a typical purge device configured for water.

Wide-bore GC columns are often used but may require jet separator or open-split interfacing to the mass spectrometer, depending upon the pumping speed of the mass spectrometer. Capillary GC columns are also used but they often require cryogenic focusing at the head of the GC column. In cryofocusing, a short section at the
head of the GC column is held at −150 °C by directing a stream of cold gas across the column, e.g. gaseous nitrogen from liquid nitrogen boil-off. After desorption from the trap is complete, this short section of column is rapidly heated to 250 °C in 15 s to desorb the analytes into a tight band at the head of the GC column. Capillary GC has the advantage of enabling direct interfacing to the ion source. A detailed reference for the application of the purge-and-trap technique can be found in the compilation of methods developed by the USEPA for sampling and analysis under Subtitle C of the Resource Conservation and Recovery Act. These methods are published under the title “Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846)” . The method for the purge-and-trap analysis of volatiles in water samples has the method number 5030B, whereas the method number for solid and solid waste samples is 5035. Another useful method for the analysis of volatiles in water has been produced by the US Geological Survey.27

Volatile water and soil samples can also be analyzed by static headspace (USEPA Method 5021) and by membrane inlet MS. In the former method, there is a single step of equilibrium partitioning between the liquid phase and the gas phase. A gaseous sample is then withdrawn for MS analysis. In membrane inlet MS, an organic-permeable membrane serves as the inlet to the mass spectrometer, and the gas chromatograph is eliminated. Because there is no separation of the analytes, this technique is more often used with quadrupole ion trap mass spectrometers that are capable of multiple stages of MS in order to provide analyte selectivity.

4.1.2 Sample Preparation for Volatiles in Air Samples

Volatile organic compounds are frequently sampled by drawing an air sample through a metal or glass tube that contains an appropriate sorbent. Synthetic polymers, e.g. Tenax®, can be used alone or in combination with activated carbon, as in USEPA Methods 5041A and 0030 for sampling and analysis of volatiles from hazardous waste incinerators28 or ambient air.29 Carbon sorbents have also been used alone30–32 for the analysis of hazardous air pollutants in ambient air. The high specific surface area of many carbon-based sorbents (100–1000 m² g⁻¹) leads to efficient trapping of volatile organic compounds. The target analytes are later thermally desorbed into a purge-and-trap device (see section 4.1.1) or directly cryo-focused onto the head of the GC column. An advantage of carbon sorbents over Tenax® is their higher thermal stability and lower background levels of interferences.

Canister-based sampling is currently the preferred method for collecting air samples for volatile organic analyses. In this method (USEPA Method TO14), a whole-air sample is drawn into a stainless-steel canister that has been surface-treated to minimize adsorptive losses.29 This method allows for a greater range of compounds to be sampled (including many polar organic compounds such as alcohols and ketones). It also allows for multiple analyses from the same air sample, and has much lower background levels than adsorbant tube sampling. For analysis, a portion of the air is removed and concentrated on a cryotrap or a sorbent bed prior to final analysis by GC/MS.

Analytical detection limits for the analysis of volatile organic compounds in air by GC/MS are frequently below 1 ppb by volume where the sample volume ranges from 1 to 5 L. Hydrolysis losses due to reaction with moisture from the air can be troublesome, e.g. hydrolysis of methyl acetate.

For volatiles analyses, the mass spectrometer is usually set to scan from m/z 35 to 260, with a scan time of 0.6–2 s per scan. The lower limit of the scan range is set to avoid the region of air (m/z 28 for N₂ and m/z 32 for O₂) and water that is entrained in the trap (m/z 18 for H₂O).

4.2 Sample Preparation for Semi-volatile Organic Analysis

4.2.1 Sample Preparation for Semi-volatiles in Water and Solid Samples

Semi-volatile organic compounds cannot be purged efficiently from aqueous media. These compounds (e.g. polyaromatic hydrocarbons, chlorinated phenols, and certain pesticides) must be extracted out of the sample using an organic solvent. For the extraction of these compounds from water, three techniques are commonly employed: separatory funnel liquid–liquid extraction; continuous liquid–liquid extraction; and solid-phase extraction. The liquid–liquid extraction techniques use an immiscible organic solvent (such as methylene chloride) to remove nonpolar organic materials from the polar matrix of water. Of course, the partitioning of organic compounds between these two media is governed by the relative solubilities in each medium (water versus organic solvent), so this approach is not useful for highly polar or ionic organic substances such as organic salts. Adjustment of pH can be used to modify the solubilities of organic acids and bases prior to extraction. For example, raising the pH to greater than 12 and then performing the extraction will extract both basic compounds and neutral compounds but will not extract acidic compounds, which will be ionic at high pH. An extraction at high pH is called a base–neutral fractionation. Similarly, extraction at low pH will remove acids and neutrals from the water sample and leave behind the basic compounds, which are acidic at low pH. By using a series of extractions at high then low pH, acidic, neutral and basic compounds can be
Separatory funnel extraction has the disadvantage of being somewhat labor intensive. An aliquot of extraction solvent is added to the separatory funnel containing the aqueous sample after the pH is adjusted. The separatory funnel is then shaken for several minutes to ensure good contact between the extraction solvent and the aqueous sample. The two phases are allowed to separate for about 10 min before drawing off each aliquot of extraction solvent. This procedure is generally repeated three times to ensure efficiency of extraction. The extraction solvent is often an organic solvent that is denser than water so that it will sink to the bottom of the separatory funnel and be drawn off through the stopcock; however, the technique can be modified for use with extraction solvents that are less dense than water. One advantage of separatory funnel extraction over continuous liquid–liquid extraction is speed (approximately 1 h for separatory funnel versus 18–24 h for continuous liquid–liquid extraction). This speed factor can be critical when analyzing for unstable compounds, e.g. organochlorine pesticides may dechlorinate under basic extraction conditions. One disadvantage of separatory funnel extractions is the propensity of some samples to form emulsions between the aqueous layer and the organic layer, which can lead to analyte losses if the emulsion is not broken. If the emulsion interface between layers is more than one-third of the size of the solvent layer, mechanical techniques such as stirring, filtration of the emulsion through glass wool, centrifugation, or sonication must be used to complete the phase separation. The USEPA Method 3510C from SW-846 is an excellent reference for liquid–liquid extraction by separatory funnel.

A continuous liquid–liquid extractor is shown in Figure 8. It is designed for extraction solvents with greater density than aqueous media, such as methylene chloride. Continuous liquid–liquid extraction devices are also available for extraction solvents that are less dense than the sample. The advantage of this device is that it continuously provides contact between the sample and fresh solvent that has been distilled from the receiving boiling flask to the condenser and back through the sample. Once the volume of extraction solvent has reached the level of the automatic siphon, this extract is siphoned to the boiling flask and the process is repeated. The USEPA Method 3520C from SW-846 is an excellent resource for this approach. The biggest advantage in using a continuous liquid–liquid extractor over separatory funnels is that emulsions are not formed in this apparatus, thus ensuring high extraction efficiencies.

One of the fastest methods for extracting organic analytes from aqueous media is the use of a solid-phase extraction cartridge. In this approach, the aqueous sample is passed through a sorbent trap or disk containing an immobilized organic material. The target organic analytes in the aqueous sample partition to the solid phase. After the sample has passed through and the sorbent washed with clean water, the analytes are eluted from the solid phase with a strong organic solvent. One of the chief disadvantages of the solid-phase extraction approach is that many nonpolar organic contaminants are likely to be bound to particulate matter in an aqueous sample and extraction recoveries from real samples are expected to be less than those determined from simply spiking organic-free reagent water. Sample particulates can also clog the solid-phase cartridge. The USEPA Method 3535 from SW-846 is an excellent resource for this approach. Figure 9 shows an example of a disk extraction apparatus.

There are two common sample preparation methods for semi-volatiles in solids, and both involve the use of an organic solvent to extract the organic compounds; one uses a continuous extraction device called a Soxhlet extractor, and the other uses an ultrasonic probe to ensure intimate contact between the sample and the extraction medium. In both approaches, the solid sample is frequently mixed with an equal weight of
anhydrous sodium sulfate to remove water and ensure good extraction solvent contact with the solid sample. The dried sample is placed in an extraction thimble or between two plugs of glass wool, and extracted using continuously renewed solvent flowing through the sample from the condenser above the Soxhlet extractor. As with the continuous liquid–liquid extractor, an automatic siphon is employed. The chief advantage of the Soxhlet extractor is that it frequently gives higher recoveries than the ultrasonic probe; however, the extraction times are much longer (16–24 h at 4–6 cycles h\(^{-1}\)). The extract is then dried with anhydrous sodium sulfate, and further processed as necessary before analysis by GC/MS (concentrated, cleaned-up, etc.). The USEPA Method 3540C from SW-846 is an excellent resource for Soxhlet extraction.

A newer method for extracting organic analytes from solid matrices is the use of solvent extraction under higher temperature and pressures than used with Soxhlet or sonication methods. These methods – using a pressurized fluid reactor (USEPA Method 3545) or a microwave extractor (USEPA Method 3546) – both involve placing the sample as a fine powder in a reaction vessel and adding an extraction solvent (typically methylene chloride, acetone, hexane, or a combination of these). The vessel is then heated to approximately 100 °C and pressurized to 1500 psi. This allows the extraction to take place in less than 15 min using only 15 mL of solvent, versus 16–18 h and 300 mL of solvent using the Soxhlet technique. Reported recoveries for these new techniques are equivalent to those achieved using the Soxhlet technique.

For all analyses for sediments, soils, and other solid media, it is customary to determine the percentage moisture in the sample and report the analyte concentrations on a dry weight basis. This approach can help to remove some of the variability associated with sampling media of high but variable moisture content.

4.2.2 Sample Preparation for Semi-volatiles in Air

A consideration for the analysis of semi-volatiles and nonvolatiles in air is the low analyte concentrations that are of concern. For example, the analysis of polychlorinated dibenzo-\(p\)-dioxins can have target detection limits below picogram-per-cubic-meter levels (pg m\(^{-3}\)). These low detection limits require large sampling volumes of the order of hundreds of cubic meters, which have led to the design of high-volume air samplers\(^{(33)}\). Because semi-volatile analytes can be associated with particulates in the air or in the vapor phase, the sampling train usually involves a combination of quartz-fiber filters to trap particulates and an adsorptive trap such as polyurethane foam. The filter and adsorptive trap are extracted by Soxhlet extraction, concentrated, cleaned up by column chromatography, and analyzed by GC/MS.

4.3 Sample Extract Clean-up

In order to achieve the low detection limits that are required for the analysis of trace organic compounds, both of using ultrasonic extraction is that the ultrasonic energy used may cause the breakdown of some organic compounds (e.g. organophosphorus pesticides). It is important to dry the sample thoroughly by mixing with anhydrous sodium sulfate prior to extraction. After each stage of extraction, the extraction solvent is removed by vacuum filtration or centrifugation followed by decanting the extraction solvent. The USEPA Method 3550B from SW-846 is an excellent resource for Soxhlet extraction.

A newer method for extracting organic analytes from solid matrices is the use of solvent extraction under higher temperature and pressures than used with Soxhlet or sonication methods. These methods – using a pressurized fluid reactor (USEPA Method 3545) or a microwave extractor (USEPA Method 3546) – both involve placing the sample as a fine powder in a reaction vessel and adding an extraction solvent (typically methylene chloride, acetone, hexane, or a combination of these). The vessel is then heated to approximately 100 °C and pressurized to 1500 psi. This allows the extraction to take place in less than 15 min using only 15 mL of solvent, versus 16–18 h and 300 mL of solvent using the Soxhlet technique. Reported recoveries for these new techniques are equivalent to those achieved using the Soxhlet technique.

For all analyses for sediments, soils, and other solid media, it is customary to determine the percentage moisture in the sample and report the analyte concentrations on a dry weight basis. This approach can help to remove some of the variability associated with sampling media of high but variable moisture content.

4.2.2 Sample Preparation for Semi-volatiles in Air

A consideration for the analysis of semi-volatiles and nonvolatiles in air is the low analyte concentrations that are of concern. For example, the analysis of polychlorinated dibenzo-\(p\)-dioxins can have target detection limits below picogram-per-cubic-meter levels (pg m\(^{-3}\)). These low detection limits require large sampling volumes of the order of hundreds of cubic meters, which have led to the design of high-volume air samplers\(^{(33)}\). Because semi-volatile analytes can be associated with particulates in the air or in the vapor phase, the sampling train usually involves a combination of quartz-fiber filters to trap particulates and an adsorptive trap such as polyurethane foam. The filter and adsorptive trap are extracted by Soxhlet extraction, concentrated, cleaned up by column chromatography, and analyzed by GC/MS.

4.3 Sample Extract Clean-up

In order to achieve the low detection limits that are required for the analysis of trace organic compounds, both
sample clean-up to remove interfering compounds and extract concentration have to be performed frequently. In the analysis of water, control of the pH during extraction can be considered as a sample clean-up step; however, further sample clean-up can be achieved through column chromatography and/or high-performance liquid chromatography. Column chromatography using silica gel, alumina, or Florisil® adsorbents is frequently used to separate crudely the target analytes according to sample polarity from interferences. An example of this approach is the use of silica gel (silicic acid) to clean up extracts and separate organochlorine pesticides from PCBs in environmental samples. In this clean-up, a hexane sample extract is added to a column containing approximately 1 g of silica gel. Increasingly polar analytes are then eluted by passing increasingly polar extraction solvents through the column. The first fraction is hexane, and it elutes the PCBs and nonpolar pesticides such as dichlorodiphenyltrichloroethane. The second fraction is eluted using 50% (v/v) ethyl ether in hexane and contains the more polar pesticides, e.g. Endosulfan I and II. This is a convenient way to separate the multicomponent PCBs from many of the single-component pesticides that will co-elute on the GC column.

Gel permeation chromatography is also used for sample clean-up; it is based upon molecular size and is most useful for eliminating high-boiling interferences that can contaminate the GC injection port and column. It is applicable to both polar and nonpolar analytes. Typical contaminants that can be removed by gel permeation chromatography include lipids, polymers, copolymers, proteins, natural resins and polymers, cellular components, viruses, steroids, and dispersed high-molecular-weight compounds. A detailed discussion of the application of many sample clean-up methods is contained in the USEPA Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846).

4.4 Chemical Derivatization

Many compounds cannot be analyzed by GC/MS because they are not amenable to GC. The major reasons for this are that these compounds do not have sufficient volatility (due to molecular weight or polarity) or they are thermally labile and hence decompose under the GC conditions. Although most of these compounds can be analyzed using liquid chromatography/mass spectrometry (LC/MS) it is still desirable to be able to analyze some of them using GC/MS. Instrument availability (GC/MS instruments usually cost much less than LC/MS instruments) and ease of use are determining factors. The most common derivatives are used to make polar compounds more amenable to GC analysis. These include methylation, trimethylsilylation, and acylation. All of these reactions form stable, volatile compounds from carboxylic acids, alcohols, phenols, amines, and thiols, and each has its advantages when analyzing for a given set of compounds. An added benefit to derivatization is that electronegative functional groups can be added to compounds to enhance detectability; at the same time, the compound is modified to make it amenable to GC analysis. An example of this is the pentafluorobenzyl bromide derivative of haloacetic acids, as shown by Equation (7):\

\[ \text{CCl}_3-\text{COOH} + C_6F_5CH_2Br \rightarrow \text{CCl}_3-\text{COOCH}_2C_6F_5 + \text{HBr} \] (7)

This reaction not only produces a volatile ester derivative from the carboxylic acid, but the addition of five fluorines to the molecule makes the detection limit for this compound in the femtogram range by NICI.

5 INSTRUMENTAL ANALYSIS CONSIDERATIONS

The final instrumental analysis in GC/MS has various requirements for the mass spectrometer, depending upon the analysis being performed. The first requirement is that the scan speed of the mass spectrometer must be sufficient to obtain at least ten scans across a chromatographic peak. This requirement is necessary to define adequately the chromatographic peak profile for quantitation. The scan speed for quadrupole GC/MS is usually 0.5–1 s per scan over the m/z range desired. This scan speed is adequate for most capillary chromatography applications where the peaks are usually not less than 20 s wide; however, for high-speed chromatography, where the chromatographic peaks can be only a few seconds wide, faster mass spectrometers such as time-of-flight instruments must be used. The mass range scanned can extend from m/z 10 to m/z 1000 on some instruments; however, few compounds with molecular weights over 500 are amenable to GC. Many analysts do not scan below m/z 35 to avoid background mass spectral peaks due to N₂ at m/z 28, O₂ at m/z 32, and water at m/z 18.

In the analysis for unknown substances, the mass spectrum can be very useful for qualitative identification by comparison to the extensive libraries of EI mass spectra. Automated search routines are available for comparison of unknown spectra to library spectra. Overlap of unknown peaks from co-eluting GC peaks give mixtures of mass spectra that in the past have been difficult to interpret. New software to deconvolute these overlapping spectra is becoming available.

In the analysis of target compounds GC/MS has been particularly successful, especially in the environmental
areas and for the analysis of drugs. In target compound analysis, frequently three strong and/or unique ions are selected as the characteristic ions to search for in a window where the retention time matches that of a standard. The relative ratios of these ions and their retention times should maximize within one or two mass spectral scans in order to confirm the presence of a target compound. Sensitivity can be enhanced by selected ion monitoring, where only a limited number of target ions are scanned. The mass spectrometer jumps between the set of target ions rather than scanning over the entire mass range. This approach avoids the dead time between ions of different m/z ratios because there is no need to scan over regions where there are no ions of interest. This technique of selected ion monitoring can improve detection limits and signal-to-noise ratios by over an order of magnitude. Tandem MS using quadrupole ion traps or triple quadrupole mass spectrometers is another technique to greatly enhance the signal-to-noise ratios for target compound analysis. In this technique, a particular target ion is selected and then dissociated to give a characteristic fragment ion. Because only these coupled ions are monitored, the chemical noise in the analysis is greatly reduced and the selectivity is greatly enhanced.

Quantitative analysis by GC/MS requires the use of both external standards and internal standards. The variability of ion optics from scan to scan mandates the use of internal standards in order to obtain good quantitation with relative standard deviations that can frequently be in the range of 5–10%. In order to obtain relative standard deviations below 5%, GC/MS frequently requires the use of isotopically labeled internal standards.

6 SUMMARY

GC coupled to quadrupole MS is one of the most powerful analytical techniques available due to its selectivity and sensitivity, but it does have limitations: the compounds must be volatile and stable in the gas phase and be able to survive ionization. However, the ability to identify and quantitate compounds that meet these criteria in complex matrices and mixtures is unmatched.

Trace Organic Analysis by Gas Chromatography with Selective Detectors

Erwin Rosenberg
Institute of Analytical Chemistry, Vienna University of Technology, Vienna, Austria

1 INTRODUCTION

Gas chromatography (GC) is nowadays one of the most universal and important separation techniques in analytical chemistry. Numerous reasons account for this fact: GC has a very wide applicability, ranging from the separation of permanent gases to the determination of petroleum products of extremely high boiling point, exceeding 100 carbon atoms in the molecule, and even highly polar or very involatile compounds can be determined after suitable derivatization (e.g. polysaccharides, organic acids and amines). Additionally, the extremely high separation efficiency of GC, reaching several tens to hundreds of thousands of theoretical plates with modern capillary columns, exceeds that of any other separation technique.

The availability of highly sensitive and selective, or, in some cases, even specific detectors was a further important reason for the success of modern GC. A number of detectors are nowadays available that are selective, or even specific, for certain compound classes or (hetero-)elements contained in a molecule and that, in the case of molecule-specific detectors, even provide positive identification of the gas chromatographically separated compounds.1–3

It is therefore appropriate to say that, if a separation can be carried out by GC, no other technique needs to be attempted. This is illustrated by the fact that more than 80% of compounds on the priority pollutant lists of the European Community (EC) and the United States Environmental Protection Agency (USEPA) may be analyzed by GC.4

Since the basic detectors of GC have already been discussed in Instrumentation of Gas Chromatography, this article will only focus on selective detectors for GC.

1.1 Classification

The classification of GC detectors is usually undertaken on the basis of their operating principle and their selectivity. The following terms and concepts are common: detectors that respond to the concentration of the analyte in the gas vector (grams per cubic meter) are called concentration-sensitive detectors. Spectroscopic detectors are a class of selective detectors which, in the ideal case, may even allow the identification of the analytes through acquisition of molecule-specific spectra. Selective detectors often allow the detection, quantitation or identification of analytes even in the presence of complex matrices and may thus significantly improve the selectivity of an analytical method.

properties. A **specific detector** ideally responds to a single compound (in the case of molecule specific detection) or at least to a limited set of compounds with similar chemical properties. A classification of the most common GC detectors is given in Table 1. It should be mentioned that the general use of the terms selective and specific is somewhat arbitrary and therefore confusing. In order to avoid any ambiguity in this context, selective is the preferred term to distinguish detectors from universal.

In Table 1, the detectors are further characterized by their selectivity, sensitivity and linear dynamic range (LDR). From a practical point of view, **selectivity** can be defined as the inverse concentration ratio of an analyte to which the detector responds selectively and a compound that is not detected with particular selectivity which produce the same signal at the detector. The **sensitivity** is the signal output per unit concentration of a particular analyte in the carrier gas (and in the case of a linear response equals the slope of the calibration graph). Together with the detector noise it determines the minimum detectable concentration of an analyte. A widely accepted value for the minimum detectable amount [= limit of detection (LOD)] is the amount of substance producing a signal-to-noise ratio (S/N) = 3. The **linear range** of the detector response is the part of the calibration graph in which there is a proportional increase of the signal with the analyte concentration in the mobile phase. It is usually a part of the **dynamic range** of the detector where the detector response increases with increasing analyte concentration, but this increase need not necessarily be proportional.

A further point to be considered in the classification of detectors is whether they are of destructive or non-destructive nature. In the latter case, multiple detectors may be used in series.

## 2 SELECTIVE DETECTORS

### 2.1 Electron Capture Detector

One of the most popular and useful detectors, particularly for environmental trace analysis, is the electron capture detector (ECD), which was developed in the early 1960s by Lovelock and Lipsky. The ECD is a detector with a selectivity towards electrophilic compounds. Halogenated compounds, nitriles, nitrites and conjugated carbonyl compounds can be detected with high selectivity over hydrocarbons, alcohols, non-conjugated aldehydes or ketones. Since many anthropogenic environmental pollutants are halogenated [e.g. halogenated solvents, organochlorine pesticides, polychlorinated biphenyls (PCBs)], the ECD is a highly useful selective and sensitive detector.

Electron capture detection is based on the fact that electrophilic compounds are able to capture slow thermal electrons that are generated from the bombardment of the carrier or make-up gas by β-electron radiation (= fast
This bombardment leads to the liberation of several hundred thermal electrons with low mean energies ($\leq 0.05$ eV) per incident electron through repeated elastic and inelastic collisions. The electrons are collected by a counter electrode (anode) to which a positive potential is applied. When an electronegative compound enters the detection region between the $\beta$-emitter and the collector electrode, the detector background current, as observed in the presence of pure carrier gas, is reduced. This diminution in detector current is the basis of the quantitative information of the ECD. Typical ECD designs have a $^{63}$Ni foil acting as a $\beta$-emitter and a collector electrode arranged concentrically. This design allows the reduction of the detector cell volume which is mandatory for use with capillary GC; however, the distance between the $^{63}$Ni foil and the anode has to be at least of such dimensions that the $\beta$-electrons are completely deactivated by collisions with the carrier gas and transferred into thermal electrons before reaching the anode. This problem is circumvented when the collector electrode is located upstream of the $\beta$-emitter foil (Figure 1a and b). However, attention has to be devoted to the detector and particularly the ionization chamber design in order to minimize extracolumn band broadening. Most commercial ECDs have detection cell volumes of 100–400 $\mu$L, which still results in additional band broadening. This can be compensated for by the addition of make-up gas at the end of the chromatographic column to maintain column efficiency, but at the price of some loss in sensitivity due to dilution. The detector can be operated either continuously [by applying a direct current (DC) voltage] or discontinuously (in pulsed mode). Pulsed-mode operation is almost exclusively used nowadays, first to minimize space-charge and contact potential effects, and second to increase the LDR of the detector. Commercially available ECDs make use of a modified pulse-sampling technique, called the variable-frequency–constant-current mode. Instead of measuring the cell current at a constant pulse frequency, the cell current is kept constant by variation of the frequency of the pulse applied to the anode for the collection of thermal electrons. Since the frequency changes with the quantity of analyte detected, the detector signal in this case is a voltage proportional to that frequency rather than a current. This mode of operation offers an extended linear range as compared with constant-frequency detection but may exhibit some deviation from linearity in the case of molecules with ultrafast electron attachment rates (e.g. CCl$_4$, SF$_6$, CH$_3$I).

For electron capture detection, the use of nitrogen as carrier gas is a good choice, provided that it is absolutely free of oxygen and other contaminants. Pure He is unsuitable, since it gives rise to the formation of unwanted metastable ions that negatively affect the detector baseline stability. Thus, nitrogen or an argon–methane mixture (5–10% CH$_4$) is added as make-up gas for the detector when He is used as a carrier gas to maximize column efficiency.

The response of the ECD to organic compounds is highly variable. It is most sensitive for halogen and nitro compounds, and detects also organometallic compounds and conjugated electrophores (e.g. benzophenones, quinones, phthalate esters) (Figure 2). The response of the ECD to halogenated compounds decreases in the order $I > Br > Cl \gg F$ but increases over-proportionally with multiple substitution at the same carbon atom (cf.

Table 2). The ECD is most frequently used for the detection of halogenated compounds (Figure 3). Through common derivatization reactions (e.g. acylation with perhalogenated acid anhydrides or acyl chlorides) polar, nonhalogenated compounds may be made accessible to both GC and highly sensitive ECD.

2.2 Nitrogen–Phosphorus Detector

The nitrogen–phosphorus detector (NPD), often also called a thermionic detector, was developed by Kolb and Bischoff in 1974$^{(7)}$ from a predecessor known as the alkali flame ionization detector (AFID).$^{(8)}$ Its construction is very similar to that of a FID. Selectivity for nitrogen- and phosphorus-containing molecules is achieved by the introduction of an alkali metal salt glass above the flame of the detector. In the presence of this thermionic source, molecules containing nitrogen or phosphorus are ionized with much higher yield than hydrocarbons. The ions formed are collected by a counter electrode and the resulting current is measured. The NPD is extremely valuable in both clinical and forensic chemistry where metabolites and drugs of abuse are determined, and also in environmental analysis where it has proven useful for the determination of organophosphorus- and nitrogen-containing pesticides.

The initial design of the NPD by Kolb and Bischoff contains an electrically heated rubidium silicate bead, situated a few millimeters above the detector jet tip and below the collector electrode (Figure 4). The bead is maintained at a negative potential which increases both the stability of the rubidium salt bead and the detector response. The source is operated at a temperature of 600–800 °C by an independent power supply. The flow of hydrogen in the nitrogen-selective mode is too low to support a flame (1–5 mL min$^{-1}$). Thus, only a plasma is sustained in the region of the alkali metal salt bead by the hydrogen and air flow. For phosphorus-selective detection, a higher flow of ca. 30 mL min$^{-1}$ of hydrogen is used. To suppress the nonselective response by hydrocarbons in the flame mode, the detector jet is grounded and the negative potential of the alkali metal salt bead deflects electrons to ground and away from the collector electrode. In the phosphorus-selective mode, phosphorus-containing fragments are only formed in the region of the alkali metal glass bead, and only...
ion-exchange mechanisms at the surface of the alkali metal salt bead. It is therefore good practice to turn off the H\textsubscript{2}/air reagent gases and to lower the temperature of the detector when it is not in use for longer periods. For the same reason, a large excess of chlorinated solvents or silylation reagents should be removed prior to injection. Although one is tempted to analyze crude extracts with little sample preparation or cleanup by GC/NPD owing to the excellent selectivity of the detector, this is generally not encouraged owing to the susceptibility of the NPD to contamination. It is also important to mention that not all nitrogen- or phosphorus-containing compounds are detected with equal sensitivity. It appears that a nitrogen–carbon bond is essential for a high response of the NPD in the nitrogen-selective mode, since, for example, esters of nitric acid (e.g. nitroglycerine) are hardly detected.

An example of the application of NPD for the monitoring of drugs of abuse is given in Figure 6.

### 2.3 Flame Photometric Detector

The flame photometric detector (FPD) is the most widely used detector for the analysis of sulfur- and phosphorus-containing substances in biochemistry, food and environmental analysis. It is based on the observation of element-specific emission of light from sulfur- and phosphorus-containing compounds in a hydrogen-rich flame. Brody and Chaney employed this principle first in 1966 for the construction of the FPD \cite{9}. Since then, this detection principle has been extended to a number of other elements, including tin, germanium, selenium, tellurium, chromium and boron \cite{10,11}.

![Figure 6](image.png)
Flame photometric detection exploits the fact that sulfur- and phosphorus-containing compounds form excited chemiluminescent species in a hydrogen-rich flame. The excited molecules emit light of characteristic wavelength on relaxation. This radiation passes through an optical filter that transmits only light of characteristic wavelength and is detected by a photomultiplier tube where the photons are converted into an electrical signal.

A typical design of an FPD can be seen in Figure 7. The end of the capillary column is inserted into the base of the FPD jet where the carrier gas is mixed with air or oxygen and combusted in a hydrogen-rich atmosphere at the burner tip. Interfering emissions from hydrocarbons occur mainly directly in the oxygen-rich flame region close to the burner tip, whereas sulfur and phosphorus emissions are more pronounced in the hydrogen-rich upper portion of the flame. Selectivity is usually enhanced by shielding the lower part of the flame by an opaque ring so that the hydrocarbon emission is prevented from reaching the photomultiplier. The extent, intensity and selectivity of the various emitting regions are highly dependent on the burner design and the individual gas flow rates, that is, not only the total gas flow but also the hydrogen/oxygen (or air) ratio, and the detector temperature. Different conditions are found to be optimal for sulfur and phosphorus detection. Sulfur detection is usually more sensitive at lower flow rates of both hydrogen (ca. 50–70 mL min\(^{-1}\)) and air (ca. 100 mL min\(^{-1}\)) whereas phosphorus requires both higher hydrogen and oxygen flow rates (both at ca. 200 mL min\(^{-1}\)). Selectivity of the detector is established by using a 392-nm band-pass filter for sulfur and a 526-nm band-pass filter for phosphorus detection where both elements have their emission maxima, respectively (Figure 8).

The theory of flame photometric detection is known only in outline. It is generally accepted that excited species are formed by several collision reactions in the flame, such as those shown in Equations (1–3):

\[
\begin{align*}
H + H + S_2 & \rightarrow S_2^* + H_2 \\
S + S & \rightarrow S_2^* \\
S + S + M & \rightarrow S_2^* + M 
\end{align*}
\]

where M is some third molecule. In the case of phosphorus, the phosphorus compounds are first decomposed to PO molecules in the flame, which subsequently are converted into HPO\(^+\) species by reactions similar to those in Equations (4) and (5):

\[
\begin{align*}
PO + OH + H_2 & \rightarrow HPO^+ + H_2 \\
PO + H + M & \rightarrow HPO^+ + M
\end{align*}
\]

It follows from the above equations that a linear dependence can be expected between the amount of phosphorus-containing compounds and the detector response. For sulfur-containing compounds, the dependence of the signal rather follows Equation (6):

\[
I = A[S]^n
\]
where \( I \) is the signal intensity, \( A \) an experimental constant, \( [S] \) the mass flow rate of sulfur atoms and \( n \) an exponential factor. Theoretically, \( n \) should assume a value of 2, but in practice values between 1.6 and 2.2 are observed. Various reasons for this deviation are known and include incomplete combustion, signal quenching by both high concentrations of co-eluting hydrocarbons or self-quenching at high analyte concentrations, competing flame reactions that also lead to de-excitation and finally structural effects.

The sensitivity of the FPD is greatly dependent on the operating conditions but is in the 5–50 pg range for sulfur-containing compounds and in the 0.5–5 pg range for phosphorus-containing compounds. The dynamic range is about \( 10^3 \) in both modes; however, as explained above, only phosphorus yields a linear response. Selectivity for phosphorus may exceed \( 10^4 \) whereas it varies greatly for sulfur compounds and is also strongly dependent on the concentration range. It is not always possible to reach this selectivity (particularly for sulfur-selective detection) because of signal quenching: co-eluting hydrocarbons can quench the detector response owing to a transient change in flame conditions or to de-excitation reactions in the emitting zone of the flame. In this respect, the dual-flame design brings a significant improvement; the typical layout of a dual-flame detector is shown in Figure 9. It consists of a two-burner design where in the first flame the analytes are burnt in a hydrogen-rich flame. The unreacted excess of hydrogen is then mixed again with air to produce a second flame which serves to excite the sulfur or phosphorus species. This two-burner design with one flame for the decomposition and combustion of the analytes eluting from the GC column and one flame for the formation of emitting species largely overcomes the quenching problems discussed above and also the problem of ‘solvent flameout’, that is, the extinction of the FPD flame by large amounts of the solvent.

Applications in which the FPD has proven to be of particular use are in the petroleum industry (detection of sulfur compounds; Figure 10), for trace sulfur compound analysis and for the detection of organophosphorus pesticides.

### 2.4 Photoionization Detector

The use of far-ultraviolet (UV) ionization (photoionization) detection evolved from initial experiments in the 1960s\(^{12,13}\) which only eventually led to a commercial instrument available in the mid-1970s, as described by Driscoll and Spaziani\(^{14}\) after solving problems related to the detector design. The PID is based on the absorption of energy by a molecule which results in electronic excitation from a (discrete) low energy level of the molecule to the higher energy continuum of the ion. The energy of such a transition is in the 5–20 eV range, and thus requires photons in the far-UV range. The ions formed are collected and detected by a collector electrode.

Early detector designs required operation at reduced pressure (typically 1–10 Torr) to maximize the photon intensity, which was not very practical. It was therefore a major breakthrough in the development of the PID when the source and the detection chamber were separated physically to allow independent optimization of both the ion formation and ion collection processes. This feature was also found to improve the stability of the PID, to increase its linear range (from ca. \( 10^4 \) to about \( 10^5 \)) and to lower the background. Still, it

---

**Figure 9** Schematic diagram of the dual FPD.

**Figure 10** FPD chromatograms of trace sulfur gases at ca. 1 ppm in nitrogen: (1) \( \text{H}_2\text{S} \); (2) \( \text{COS} \); (3) \( \text{CH}_3\text{SH} \); (4) \( \text{CS}_2 \). (a) 5-\( \mu \)L on-column injection (10 pg \( \text{CH}_3\text{SH} \)); (b) 100-\( \mu \)L on-column injection (200 pg \( \text{CH}_3\text{SH} \)). FPD with 393-nm filter; column, 100% polydimethylsiloxane, 30 m x 0.53 mm ID, 2.85 \( \mu \)m film thickness; carrier gas, \( \text{He} \), 2.75 mL min\(^{-1}\); makeup gas, \( \text{N}_2 \), 50 mL min\(^{-1}\); air, 60 mL min\(^{-1}\). form the ionization chamber by a metal fluoride window.

Thus, the wavelength emitted from a 10.2 eV source is ca. 121 nm.

Equation (7): calculated from the source energy (in electronvolts) from

Employed. The wavelength (in nanometers) can be

Sources of different energies are

MgF2, CaF2 or SrF2). Sources of different energies are employed.

It can be understood from the above equations that the

detection of ions that result from rearrangement or

or elimination reactions, R+*, is also possible). The processes

In Equations (13–15) compete with the photoionization of the analytes (quenching reactions):

A + hv \rightarrow A^+ + e^- \quad (8)

or indirectly [Equations 9–12]:

C + hv \rightarrow C^* \quad (9)

C^* + A \rightarrow A^+ + e^- + C \quad (10)

A + hv \rightarrow A^* \quad (11)

A^+ \rightarrow A^{++} + e^- \quad (12)

The smaller detection cell volumes can still be used with capillary columns without causing unacceptable peak broadening, but the use of a makeup gas to reduce peak broadening or operation at higher column flows (≥2 mL min⁻¹) is recommended. Detector cell volumes between 150 and 250 µL are preferably used with packed columns. Precise thermostating of the detector can minimize baseline drift.

The process of photoionization can be described by a number of reactions in which the analyte A and the carrier gas molecules C interact with each other and with photons of energy hv. Ionization can occur either directly [Equation 8]:

\[ A + hv \rightarrow A^+ + e^- \]  

or indirectly [Equations 9–12]:

\[ C + hv \rightarrow C^* \]  

\[ C^* + A \rightarrow A^+ + e^- + C \]  

\[ A + hv \rightarrow A^* \]  

\[ A^+ \rightarrow A^{++} + e^- \]  

(8)

(9)

(10)

(11)

(12)

It can be understood from the above equations that the detector response depends to a certain degree on the presence of electron-capturing impurities in the carrier gas (e.g. oxygen) and also the choice of carrier gas, which, through collisional de-excitation, can influence the sensitivity.

When using a 10.2 eV photon source, most organic molecules are ionized. Exceptions are the permanent gases, C1–C4 hydrocarbons, methanol and acetonitrile (which, therefore, makes them suitable solvents for GC analysis, cf. Table 3) and the chloromethanes. For aromatic compounds, the sensitivity of the PID can be up

Figure 11 Schematic diagram of a PID.

has to be borne in mind that the ionization efficiency is only about 0.001–0.1%, depending on the analyte. The PID is thus a virtually nondestructive detector and particularly useful for applications where nondestructive detection is required and/or in combination with a second detector. Additionally, it does not require any reagent gases and usually also no makeup gas, which makes it ideally suited for small, portable instruments. The detector selectivity can be tuned to a certain extent by changing the excitation source and thus the wavelength (energy) of exciting radiation. As a drawback of the PID, its compound-dependent response, requiring individual calibration for each analyte, has to be mentioned. A generic design of the PID is shown in Figure 11. A typical PID has two functional units: an excitation source and an ionization chamber. The former consists of a UV source which in most cases is a discharge lamp, filled with an inert gas or gas mixture at reduced pressure that emits monochromatic light of a characteristic wavelength or energy, depending on the choice of the fill gas (e.g. Ar, Xe, Kr) and the window material (e.g. LiF, MgF2, CaF2 or SrF2). Sources of different energies are commercially available (with, e.g. 9.5, 10.0, 10.2, 10.9 and 11.7 eV), but the 10.2 eV source is the most commonly employed. The wavelength (in nanometers) can be calculated from the source energy (in electronvolts) from Equation (7):

\[ \lambda(\text{nm}) = \frac{1234.5}{E} (\text{eV}) \]  

(7)

Thus, the wavelength emitted from a 10.2 eV source is ca. 121 nm.

The discharge compartment is mechanically separated form the ionization chamber by a metal fluoride window which is optically transparent in the far-UV range. The effluent from the GC column passes through the thermostated ionization chamber and between the two electrodes which are positioned on the opposite ends of the ionization chamber. Between these, an electrical field is applied to accelerate and to collect the ions that are formed by photoionization. The current is amplified by an electrometer and read out. Typical ionization chamber volumes are between 40 and 250 µL. The smaller detection cell volumes can still be used with capillary columns without causing unacceptable peak broadening, but the use of a makeup gas to reduce peak broadening or operation at higher column flows (≥2 mL min⁻¹) is recommended. Detector cell volumes between 150 and 250 µL are preferably used with packed columns. Precise thermostating of the detector can minimize baseline drift.

The process of photoionization can be described by a number of reactions in which the analyte A and the carrier gas molecules C interact with each other and with photons of energy hv. Ionization can occur either directly [Equation 8]:

A + hv \rightarrow A^+ + e^-  

(8)

or indirectly [Equations 9–12]:

- for substituted benzenes with ring activators (= electron-releasing groups) and decreases with ring deactivators (= electron-withdrawing groups); exception: halogenated benzenes

to 50 times higher than that of the FID, and for aliphatic compounds, a gain in sensitivity of 5–10-fold over the FID can still be realized. There are collections of data on the response of a great number of compounds relative to benzene, which allows several empirical conclusions to be drawn on the basis of this and other data. Generally, an increase in sensitivity is observed as the carbon number increases. The other relationships are summarized in Table 4.

As an example, the analysis of gasoline components using PID and the different selectivities that can be obtained at different lamp energies are shown in Figure 12(a–d).

2.5 Electrolytic Conductivity Detector (Hall Detector)

The electrolytic conductivity detector (ELCD) for GC was first reported by Piringer and Pascalau. The ELCD has particularly been utilized for the selective detection of sulfur, halogen and nitrogen compounds. The commercial introduction of this detector was in the mid-1960s, following further development by Coulson.

The basis of this detector is the catalytic combustion of the analytes in a furnace at high temperatures (ca. 900 °C) with the addition of reagent gases. This reaction converts, e.g. halogenated compounds into halo acids which are swept from the reactor into a gas–liquid contactor where they are dissolved in an appropriate solvent (e.g. 1-propanol). The strong acids increase the electrolytic conductivity of the solvent which is then passed through a conductivity cell where its conductivity is measured (see the block diagram in Figure 13).

A number of improvements were introduced to this detector by Hall, which led to the design shown
in Figure 14. Following the reaction cell where the catalytic conversion of the analytes to the detectable species takes place, these are led into a small-volume, concentric cylinder cell for mixing, separation and detection of the detectable reaction products. The solvent and the gaseous reaction products are merged in a small polytetrafluoroethylene (PTFE) tee. The initially heterogeneous gas–liquid mixture forms a smoothly flowing liquid phase which passes by the electrodes of the conductivity cell. The electrolyte stream is driven downwards by the circulation of the collecting solvent through a pump and the pressure that is executed by the carrier gas. Different ways of measuring the conductivity exist of which the differential detector design is the most useful. It employs two conductivity cells in series where the first cell measures the conductivity of

the solvent while the second measures the conductivity of the solvent plus the reaction products. Measuring the difference of the two conductivities eliminates to a great extent response variations caused by temperature differences and changes/drift in the concentration of the solvent. The solvents mostly employed nowadays are 1-propanol and methanol, either alone or in admixtures with water. Pure water is hardly any longer used as solvent. The lower alcohols, being themselves very weak acids, are used to suppress the dissociation of weak organic acids (e.g. carboxylic acids, phenols) and thus to render the detector selective for the strong inorganic acids formed by the cata lytic conversion of the analytes. Furthermore, 1-propanol exhibits a very low solubility for carbon dioxide from the catalytic decomposition so that the detector does not respond to carbon. Most detectors recirculate the conductivity solvent through a closed-loop system. In order to achieve a low background conductivity and to regenerate the solvent, an ion-exchange resin bed is used. The selectivity of the detection can be increased by using an element-specific potentiometric electrode instead of the standard conductivity cell.

The ELCD can be operated in three principal detection modes with the detected species as given:

- halogen mode, HX (where X is usually Cl);
- sulfur mode, SO2;
- nitrogen mode, NH3.

The selectivity of the ELCD is controlled by the operating conditions of the detector. When, for example, halogen compounds are to be detected, a nickel catalyst, hydrogen reaction gas, a reactor temperature of 850–1000°C and 1-propanol are used. Under similar conditions, NH3 is formed from nitrogen-containing compounds (see Table 5).

The most relevant practical limitations of the ELCD are its poor linearity and peak shape. Poor linearity in most cases is a consequence of neutralization of the conducting solvent when, e.g. its capacity is exhausted. Neutralization problems can be recognized by the typical negative dips before and after the elution of a peak. Peak tailing can often be traced back to contamination of the scrubber or the transfer line, deactivation of the catalyst or the presence of interfering reaction products that are not removed by the scrubber. Further factors affecting detector stability and response are the absolute flow rate of the conductivity solvent and its stability. Practical operation conditions usually represent a compromise since low solvent flow rates increase sensitivity but at the same time increase noise due to pulsation of the solvent delivery system.

The ELCD offers high selectivity and sensitivity under optimized conditions. Detection limits down to 1 pg of chlorine, nitrogen and sulfur can be reached with a dynamic range of $10^3$–$10^5$. The selectivity of the detector varies between $10^4$ and $10^9$ depending on the heteroelement to be detected and the operating conditions. Compared with the FPD in the sulfur mode, the ELCD has similar or greater sensitivity and selectivity, and compared with the ECD, the ELCD not only has a significantly greater selectivity for chlorine-containing compounds, but also a more uniform response on a molar basis (Figure 15a and b).
selectivity for oxygen is achieved by selective formation of CO only from oxygen-containing molecules in a first cracking step and reduction of the CO formed to methane which is detected by a conventional FID.\(^{(22)}\) A further interesting, although hardly used, detector is the far-UV absorbance detector that can detect all compounds absorbing far-UV radiation in the 120–145 nm range.\(^{(23)}\)

### 3 DETECTORS ALLOWING SELECTIVE RECOGNITION

The detectors discussed so far still have, despite their selectivity, two shortcomings for practical applications: their selectivity is limited in most cases, and they do not provide specific and sufficient information to elucidate the identity of a chromatographically separated compound. This information can, under optimal conditions, be provided by spectroscopic detectors that allow the selective recognition and identification of the separated compounds. The combination of (gas) chromatographic separation and spectroscopic detection is usually referred to as a hyphenated technique. Gas chromatography/mass spectrometry (GC/MS), gas chromatography/Fourier transform infrared (GC/FTIR) spectrometry and gas chromatography/atomic emission detection (GC/AED) are nowadays the most common and most powerful hyphenated techniques used for the identification and structural elucidation of unknown compounds. They are available now as easy-to-use benchtop instruments which constitute the basis for their acceptance in the routine laboratory. The ease of use of these hyphenated techniques is to a great extent due to the development of capillary column chromatography, which is nowadays almost exclusively used. The use of capillary columns with their significantly reduced carrier gas flow rates in many cases eliminates the need for a dedicated interface (with all related problems and shortcomings) and allows a direct connection of the capillary column outlet to the spectrometer, even if this is operating under vacuum as is the case for GC/MS.

The hyphenated techniques (GC/MS, GC/FTIR, GC/AED) are very often used as stand-alone systems. Even more powerful is the combination of two hyphenated techniques [ideally performed on one chromatograph\(^{(24)}\)] which is done occasionally and increases the information content of the techniques by combining the data from the two spectroscopic techniques which allows one to confirm or to exclude suspected analytes.\(^{(25)}\) Owing to the nondestructive nature of FTIR detection, GC/FTIR may be combined with MS detection in either the serial or parallel mode. When FTIR and MS detection are operated in parallel mode, the column effluent has to be split between the two detectors.

---

**2.6 Other Selective Detectors**

There are a number of other selective detectors that permit element- or compound class-selective detection, but have not been included owing to their less widespread use. These include the sulfur chemiluminescence detector (SCD),\(^{(20)}\) which is one of the most selective and sensitive sulfur detectors, the thermal energy analyzer (TEA),\(^{(21)}\) designed for the ultratrace determination of nitrosamines, and also based on chemiluminescence detection after low-temperature pyrolysis of the analytes, and the oxygen-sensitive flame ionization detector (O-FID), in which
Owing to the lower sensitivity of FTIR detection compared with MS detection, the split ratio should favor the FTIR spectrometer, e.g. 10:1 (Figure 16a and b). Similarly, the two destructive techniques AED and MS may only be operated in parallel mode; however, owing to the excellent sensitivity of AED for most relevant elements, the split ratio can be close to unity. The properties and characteristics of the individual spectroscopic detectors are discussed in the following sections.

### 3.1 Gas Chromatography/Mass Spectrometry

The coupling of GC and MS was first described in the mid-1950s. The commercial success of this technique, however, only came with the introduction of capillary column GC in the early 1970s that eliminated the need for a special interface and brought a significant reduction in the pumping capacity necessary to meet the high vacuum requirements for MS detection. At the same time mass analyzers, based on either the quadrupole mass filter or the ion trap principle, became available and allowed the construction of compact, benchtop instruments.

The principle of GC/MS will be explained based on the quadrupole mass filter serving as an example. The sample molecules exit from the GC column and are usually led through a heated transfer line from the gas chromatograph directly into the ionization chamber (ion source) of the mass spectrometer. In the ion source, both molecular and fragment ions are formed and extracted and accelerated into the mass analyzer through the application of a high voltage. In the mass analyzer, the ions are separated according to their mass-to-charge ratio (m/z). The separated ions are detected (after conversion into photoelectrons) by an electron multiplier and the resulting mass spectrum is recorded as a line spectrum of the ion intensity (y-axis) against their m/z ratio (x-axis).

Two different ionization techniques are commonly employed in MS detection for GC: electron impact (EI) and chemical ionization (CI). The most frequently used technique is EI where the molecules are bombarded with electrons with a kinetic energy of 70 eV emitted from a heated rhenium or tungsten filament. The collision of an electron with the molecule forms a radical ion by the expulsion of an electron (M+). This radical ion has an excess energy of about 60 eV, which is enough to dissociate further into fragment ions, radicals and neutral species, thereby producing a characteristic fragment ion pattern. As a rule of thumb, the most labile bonds in the molecule are cleaved and those fragment ions occur with highest abundance that are the most stable. Owing to the low pressure in the ion source region (ca. $10^{-5}$ Torr $= 1.33 \times 10^{-3}$ Pa), association between molecules and fragment ions does not occur.

Many substance classes, e.g. alkanes, fatty acids and steroids, undergo extensive fragmentation. This can be to such an extent that the molecular ion peak is detected at only very low sensitivity or is not detectable at all. This renders unambiguous identification of homologous compounds difficult since the information on the molecular mass is not available. A further disadvantage is that fragment ions at lower masses ($m/z < 100$) are less characteristic for a molecule and make selective detection difficult.

For the detection of compounds that exhibit strong fragmentation in EI, CI is the preferred method. The latter is a soft ionization technique where the analyte molecules are ionized indirectly through gas-phase ion–molecule reactions. For this purpose, a reagent gas such as methane or isobutane is introduced into the ion source at relatively high pressure (ca. 1 Torr $= 133$ Pa) and ionized under EI. The ionized reagent gas usually transfers a proton to the analyte upon collision, thereby forming the characteristic [M + H]$^+$ quasi-molecular ion. Owing to the low energy of this reaction, intensive quasi-molecular ions occur which often are the base peak (= the most intense peak) of the spectrum (Figure 17a and b). This allows in most cases the determination of the molecular mass of an unknown. CI is also particularly useful for highly chlorinated compounds (PCBs, dioxins, toxaphenes, organochlorine pesticides) which can be detected in the negative ion mode with excellent selectivity and sensitivity owing to the high electron affinity of these compounds. Over the past years, the operation of GC/MS in the CI mode has greatly gained in simplicity and stability so that GC/CI/MS may nowadays be considered an excellent technique for sensitive quantitative analysis.
The ions formed in the ion source are accelerated into the mass analyzer where they are separated according to their $m/z$ values. In the case of a quadrupole mass filter this is achieved by adjusting the voltages and frequency applied to the four rods of the quadrupole. The mass filter thus becomes permeable for ions only of a defined $m/z$ ratio while ions of other $m/z$ ratios are not transmitted. A mass spectrum is recorded by variation of the respective voltages with time and is called a scan. The resulting mode of operation, full-scan mode, is required when unknown substances are to be identified according to their specific fragmentation pattern. In this mode, the mass spectrometer is scanned continuously while the analytes elute from the column. The summation of all individual ion intensities in a spectrum results in the total ion current which is plotted against the retention time or scan number as a total ion chromatogram or reconstructed ion chromatogram. The total ion chromatogram is similar to the signal of a universal detector, e.g. the FID, but with greatly different relative intensities. All spectra recorded during a chromatographic run are stored and may be retrieved for identification purposes. Nowadays, this is almost exclusively done by computer-assisted comparison with existing spectral libraries which contain far more than 100,000 reference spectra [e.g. the National Institute of Standards and Technology (NIST) or the Wiley spectral library]. From the stored data, both compound- and class-specific information can be obtained. The latter can be obtained by extracting from the three-dimensional data array (intensity of the ions of different $m/z$ ratios as a function of time) the intensity of an $m/z$ ratio characteristic for the compound class monitored (e.g. the molecule ion of a group of isomers or a characteristic fragment ion for a series of homologs). The resulting trace of a fixed $m/z$ ratio over time is called an extracted ion chromatogram (EIC), and it provides compound class selectivity from data acquired in the full-scan mode, but no increase in sensitivity. If highly selective and sensitive quantitative analysis is to be carried out, MS is operated in the selected ion monitoring (SIM) mode. In this mode of operation, the mass spectrometer settings are adjusted in such a way that only a limited number of ions are monitored (typically two to four) by stepwise adjustment of the voltages during one cycle. Hence the time that is available for counting the abundance of a selected few ions is significantly longer than in the full-scan mode (typically by a factor of 50–100). This results in a greatly improved sensitivity and reproducibility and makes quantitative detection in the low-picograms range possible (Figure 18a–c).

**Figure 17** Mass spectra of trimethylsilylated clenbuterol obtained with (a) EI and (b) CI using methane as reagent gas. TMS, trimethylsilyl.

**Figure 18** (a) Enlargement from a GC/MS full-scan analysis of a municipal incinerator fly ash for tetrachlorinated dibenzo-p-dioxin (TCDD) compounds and (b) SIM chromatogram of the same sample, indicating the presence of some TCDD isomers. (c) SIM chromatogram at $m/z$ 334 for the same sample to which $^{13}$C-labeled TCDDs were added for quality control purposes. [Redrawn from R.E. Clement, E.J. Reiner, in *Detectors for Capillary Chromatography*, Chemical Analysis, eds. H.H. Hill, D.G. McMinn, John Wiley & Sons, New York, 351, Vol. 121, 1992.]
An extremely valuable feature of GC/MS is that it allows the use of isotopically labeled internal standards to improve the accuracy and precision of quantitative analysis. These compounds have physical and chemical properties practically identical with those of the original analytes, except that e.g. a number of hydrogen or carbon atoms have been replaced by deuterium or ¹³C atoms. These isotopically labeled standards are added to the sample before any pretreatment or clean-up step. As sample preparation is performed, both the deuterated and the undeuterated standard behave similarly so that any systematic errors of the method are compensated. Quantitation is then performed in the SIM mode by monitoring selected ion intensities of the analyte and ratioing these to the ion intensities of the isotopically labeled internal standards. The application of this highly useful quantitation technique is restricted only by the limited availability of isotopically labeled standards.

3.1.1 Gas Chromatography with Other Mass Spectrometer Types

Owing to its robustness, its compact construction and competitive price, the quadrupole mass spectrometer is most frequently used in GC/MS instruments. It has, however, the following shortcomings: quadrupole mass filters are low-resolution spectrometers (they are usually operated at ‘unit resolution’, which means that two neighboring peaks with one unit mass difference can still be separated, but they are not capable of high resolution). Their scanning speed is limited (allowing from <1 to a maximum of 10 scans per second, depending on the scan range and the chosen acquisition parameters). The transmission decreases strongly with increasing m/z ratio and is limited to about 1000 for most commercial instruments (which is still sufficient for most GC/MS applications). The sensitivity in the full-scan mode is ca. 100 times lower than in the SIM mode.

Some of these limitations are overcome by particular mass spectrometer types. The ion-trap mass spectrometer has a number of attractive features and has thus gained much in importance over the past years. An ion-trap mass spectrometer can be thought of as a quadrupole mass filter whose rods are closed to a circle. It consists of a central, circular ring electrode and two further electrodes as caps on the top and bottom side of the ion trap to which the respective alternating current (AC) and DC voltages are applied. The ions that are ionized by a conventional EI (or, less frequently, a CI) source enter the detector through an electronic gate which can be opened or closed by application of an appropriate voltage. The ions are stored in the ion trap by the application of a radiofrequency (RF) voltage to the ring electrode. The ion trap detector is operated at a relatively high pressure (10⁻²–10⁻³ Torr) to dampen the motion of the stored ions and to avoid their immediate loss by ejection out of the ion trap. Analysis of the ions is performed by applying an RF voltage sweep. This successively destabilizes ions of different m/z ratios on their orbit so that they are ejected from the trap and are detected by the electron multiplier. The automatic gain control of modern ion-trap detectors controls the amount of ions in the trap and thus minimizes signal suppression or distortion due to space-charge effects. Ion trap detectors are extremely sensitive and allow, owing to the storage of all ions and successive ejection to the detector during one scan, the acquisition of full-scan spectra in the low-picogram range with a dynamic range of up to 10⁶. Further advantages of the ion-trap detector are its compact construction and the less stringent vacuum requirements, allowing reasonably priced instruments to be built. Ion trap detectors furthermore offer the possibility of multi-dimensional MS, MS/MS (or MS³) and even multiple MS (MSⁿ). This is achieved by ejecting all ions but those of a selected m/z ratio from the trap and inducing, through the application of an RF voltage sweep, fragmentation of these selected ions. The fragments of this parent ion can be detected in a subsequent scan (Figure 19). If required, this experiment can be repeated to obtain MSⁿ mass spectra. This feature significantly increases the structure elucidation capabilities for unknowns by GC/MS, or greatly improves the S/N and thus detectability since the background is virtually suppressed completely. However, it is only possible to obtain daughter ion spectra. Operation in parent-ion or linked scan mode remains reserved for the significantly more complex and more expensive triple quadrupole instruments.

![Figure 19 Mass chromatogram of malathion in orange peel extract at the 30 pg (abs.) level, recorded at m/z 127 from collision-induced dissociation in the trap of m/z 173. The inset shows the mass spectrum of the parent compound. [Courtesy of Varian Chromatography Systems, Walnut Creek, CA, USA.](Image)]
High-resolution GC/MS (with resolution $R > 5000$) requires the use of significantly more complex instrumentation, such as double-focusing instruments. These consist of an electrostatic analyzer and a magnetic field separator. The electrostatic analyzer provides energy focusing: the ions with a particular $m/z$ ratio but different kinetic energy are deflected towards the same focal point. This significantly improves the mass resolution of the instrument without a decrease in signal (as opposed to reducing the slit width), since the mass resolution of the magnetic separator is critically dependent on the energy and the divergence of the flight path of the entering ions. With a double-focusing instrument, either high resolution or accurate mass determination is possible. This is particularly useful, e.g. in the ultratrace determination of dioxins in complex environmental matrices.

A further type of mass spectrometer, recently introduced for GC detection and capable of both extremely sensitive detection and, in principle, high mass resolution is the time-of-flight (TOF) mass spectrometer. In the TOF mass spectrometer, ions are formed in a pulsed ion source and accelerated by the application of a potential $V$ through a field-free flight tube towards the detector. The time $t$ that the ions need to arrive at the detector (in a distance $d$) is measured and related to the $m/z$ ratio according to Equation (16):

$$ t = d \sqrt{\frac{m}{2zeV}} \quad (16) $$

It is evident from this equation that a pulsation or gating of the ion source is required to let only ions of a fixed $m/z$ ratio arrive at the detector at a certain time, and that the mass resolution is dependent on the pulse width. This factor, together with the speed of the counting electronics, has until recently limited the achievable resolution to a few hundred; however, instruments of significantly higher resolution (ca. 5000) are nowadays available. TOF mass spectrometers offer the advantage of a very high sensitivity in the ‘scan’ mode since all ions generated arrive at the detector, and they excel in the absence of mass discrimination effects where higher masses are transmitted to a lower degree than lower mass ions.

### 3.2 Gas Chromatography/Fourier Transform Infrared Spectroscopy

Coupled GC/FTIR spectroscopy provides the acquisition of mid-infrared (IR) spectra (typically in the spectral region 400–4000 cm$^{-1}$) of the peaks as they elute from the chromatographic column. GC/FTIR is a useful alternative and complement to GC/MS detection since it is a non-destructive technique (and may thus be coupled in series with other detectors, e.g. GC/MS), it allows the discrimination of isomers and offers the possibility of functional group-selective detection (through recording of the absorbance at frequencies characteristic of functional groups of the molecule).

FTIR detection for GC is most frequently done with the lightpipe or flow cell approach that was introduced in the early 1980s by Azarraga$^{27}$. The lightpipe is a flow cell through which the column effluent passes and that is located in the beam of the FTIR spectrometer (Figure 20). It is a heated, internally gold-coated glass tube with IR-transparent windows (made from, e.g. KBr or ZnSe) which is connected to the chromatographic column via a heated transfer line. The internal gold coating provides maximum reflection of the IR radiation which has to be transmitted through the lightpipe. Typical dimensions of the lightpipe are 1 mm ID and 1–20 cm length, resulting in a detection cell volume of 80–160 µL. It is evident from these figures that the lightpipe volume has to be carefully matched to the GC system and operating parameters. It always represents a compromise between maximum sensitivity (achieved by larger lightpipe dimensions) and minimum distortion of chromatographic resolution (requiring smaller detection cell volumes), particularly when using capillary columns. The simplicity of this approach has made the lightpipe interface the most frequently used for GC/FTIR measurements. Its sensitivity, however, is not adequate for highly sensitive detection at the ultratrace level, since ca. 5–100 ng of a strong IR absorber are required for a good-quality spectrum. The spectra acquired during the elution of a peak are co-added and may be library searched for identification purposes. However, dedicated
gas-phase libraries are necessary since IR spectra depend strongly on the physical state of the compound.

There exist also other approaches for coupling FTIR detection to GC separation. These are not as experimentally simple, though, and therefore far less popular. They rely on the deposition of the column effluent on a ZnSe plate that is cooled by liquid nitrogen to 77 K. While the analytes elute from the GC column, the ZnSe plate that is mounted on an \( x-y \) translation stage is moved with a constant linear velocity. The analytes are thus immobilized along a line on the ZnSe plate and transported into the beam of a dedicated IR microscope that focuses the IR beam to a diameter that matches the sample spot dimensions (ca. 100 \( \mu \)m). The chromatogram in time is thus translated into an (immobilized) chromatogram in space and compounds may be detected in near real time. Owing to the immobilization of the analytes on the ZnSe plate, longer scanning times can be applied and consequently significantly improved detection limits can be achieved (20–100 pg are often sufficient for an IR spectrum). The IR spectra are comparable to those existing in widely available condensed-phase libraries. However, highly volatile compounds are not detectable since they are not efficiently trapped on impacting the liquid nitrogen-cooled ZnSe plate.\(^{(28)}\)

Data acquisition in GC/FTIR detection is still highly demanding owing to the large number of data points (a spectrum recorded between 4000 and 400 cm\(^{-1} \) with a resolution of 4 cm\(^{-1} \) has 900 data points) and the high scanning speed of modern FTIR spectrometers (typically 1–10 scans s\(^{-1} \)). To obtain an on-line-signal or a functional group chromatogram, a fast Fourier transformation (FFT) of a limited subset of the data acquired, e.g. with a Michelson-type interferometer, is performed. The FFT of the interferograms with a reduced number of data points is substantially faster, but results in spectra with lower resolution (e.g. 8 or 16 instead of 4 cm\(^{-1} \)) which are, however, available practically on-line. Also, functional group chromatograms can be plotted as the absorbance calculated for a spectral window of interest (e.g. in the carbonyl band region) versus time to detect the presence of analytes carrying this functional group (Figure 21a–d).

The most convincing examples of GC/IR analysis originate from the field of natural products analysis: since fragrances and natural substances are very often isomers, having the same molecular formula but different structure, MS is often not able to differentiate these isomers whereas IR detection succeeds (e.g. Figure 22a–c).

### 3.3 Gas Chromatography/Atomic Emission Detection

Of the different atomic spectroscopic techniques to be coupled to GC, only atomic emission spectroscopy has gained greater importance through the availability of commercial instrumentation since the late 1980s.\(^{(29,30)}\) The basis was already laid in the mid-1960s through the work of McCormack et al.\(^{(31)}\) and Bache and Lisk\(^{(32)}\) on plasma emission spectrometric GC detection. Being the most recent development in the group of hyphenated techniques, the AED provides, in contrast to GC/MS and GC/FTIR, element-specific rather than compound-specific detection and thus ideally complements these detection techniques.

In AED, the chromatographic effluent is introduced into a helium-sustained microwave-induced plasma (MIP). In the plasma, the analytes are completely atomized, partially ionized and excited. On returning to a lower energy level, the atoms or ions emit characteristic radiation which is recorded by a diode-array spectrometer. Different ionization, recombination and energy transfer processes contribute to the excitation of the atoms liberated from the analytes. The use of He as a plasma gas is practical since it is often also applied as a GC carrier gas and is

particularly advantageous in AED, since it has a simpler spectral background and a significantly higher excitation energy than Ar (the first ionization energy is 24.59 eV vs 15.76 eV for argon). Hence practically all elements can be excited efficiently, including the nonmetallic elements. Comparatively low He flow rates (30–300 mL min\(^{-1}\)) and low power (ca. 60 W) are required to sustain the plasma, but it is therefore not very resistant to larger sample loads. The plasma is powered by a microwave generator operating at 2.45 GHz and sustained in a 1 mm ID quartz tube which is centered inside the microwave cavity. In the plasma, temperatures of 3500–4000 K are reached, at which the analytes are efficiently atomized and excited. The characteristic element-specific radiation is detected in an axial viewing configuration by a diode-array spectrometer including a holographic grating as dispersion element. The accessible spectral range is from ca. 160 to 800 nm. As the whole spectral range cannot be recorded by the diode-array detector with acceptable resolution, only portions of the emission spectrum in the region of emission lines of interest are recorded at a time (Figure 23). Useful sets of emission lines are, e.g. those of C, H, Cl and Br, which can be measured simultaneously in the 470–496 nm range, or C, S, Se and N, which can be measured in the 170–196 nm range. The recording of elemental chromatograms at emission lines in largely different regions of the spectrum requires separate chromatographic runs. Separate chromatographic runs also have to be made when the required plasma dopant gases that are added to the He in small quantities (also called scavenger gases) are different. The detection of phosphorus, for example, requires only hydrogen as reagent gas and makes its simultaneous detection with C, N and S which require both hydrogen and oxygen as reagent gases impractical, although the emission lines of these elements all lie within the same spectral range.

The sensitivity of AED can vary strongly between elements (cf. Table 6). AED is an excellent method...

Figure 23 Schematic diagram of a GC/AED instrument.
for sulfur, carbon and metals, but less sensitive for nitrogen and the halogens, especially when compared with the NPD and the ECD, respectively. It offers, however, a number of practical advantages which make its use very convenient for particular applications. The response is in principle compound independent. Owing to the complete atomization of the analytes in the plasma, the signal no longer depends on the molecular structure of the compound to be quantified. This offers the possibility of calibration with a substitute standard when the compounds to be quantified are not available as pure substances or are hazardous. Moreover, empirical formulae may be calculated, which provides complementary and useful information for the interpretation of mass spectral data. The selectivity of AED very often exceeds that of the corresponding element-selective detector such as the NPD or ECD, and also the linear range is often larger. It is also able to differentiate between the halogens chlorine, bromine, iodine and fluorine, which is not possible with any other selective detector. AED is not only able to detect virtually all elements of the periodic table including oxygen, but also some of the stable isotopes, such as $^{2}$D, $^{13}$C and $^{15}$N, based on the slight shift of molecular band position (although at lower sensitivity and fair selectivity over the more abundant isotope).

AED has found broad use in the petroleum industry, where its capability of detecting sulfur-containing, oxygenated and organometallic compounds is particularly useful, and in environmental analysis, where the combination with MS detection greatly improves the interpretability of the data (Figure 24a and b).

### 3.4 Other Atomic Spectroscopic Detectors for Gas Chromatography

While GC/AED, due to its commercial availability, is probably the most frequently applied atomic spectroscopic detector, a number of other less popular techniques are available for atom spectroscopic GC detection. These include atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS) and inductively coupled plasma mass spectrometry (ICPMS).
AAS is inherently a metal-specific detection method where GC is a sample introduction technique for either volatile organometallic species (such as organic compounds of lead, tin, mercury, selenium or arsenic) or metal species that can be rendered volatile through derivatization or complex formation. AAS requires the analytes to be efficiently atomized so that the free atoms can be excited. The absorbance of monochromatic radiation characteristic for the element to be detected is measured, and the signal is proportional to the analyte concentration and the optical path length according to the Lambert–Beer law. While the simplest way of coupling GC to AAS is to introduce the GC column outlet directly into the base of an only slightly modified burner of a conventional flame spectrometer, this method suffers from poor sensitivity owing to the short residence time and the comparatively large dilution of the analytes in the detection zone. A more efficient method is the coupling of GC to electrothermal (graphite or quartz furnace) AAS. In this case, a T-shaped quartz tube or a modified graphite furnace is used. The sample is introduced through a heated transfer line into the center of the graphite or quartz furnace. Sometimes the addition of a reactive gas such as hydrogen is useful for enhancing the sensitivity. Detection limits of 10–100 pg of analyte can be reached in favorable cases (e.g. for tin, lead and arsenic). The most interesting applications are from the field of speciation analysis where, e.g. ionic alkyltin compounds are determined after derivatization with a suitable Grignard reagent (Figure 25).

AFS detection for GC combines the selectivity of AAS with the multielement detection capabilities of atomic emission techniques. The theoretically wide applicability
is in practice limited by the availability of suitable simple and intense excitation sources and by the sparseness of commercial instrumentation. Typical atom reservoirs are the cells also used in AAS with some modifications, e.g. premixed laminar argon sheathed miniature diffusion flames and heated quartz and graphite atomizers. The use of conventional line sources (hollow-cathode and electrodeless discharge lamps) allows detection limits in the 10–100 pg range to be achieved for most metallic elements. Extreme detection limits down to sub-picogram levels have been reported when using pulsed tunable dye lasers pumped by an Nd: YAG laser or an excimer laser. However, the extremely high costs and the difficulty of operation prevent this technology from being widely applicable.

The inductively coupled plasma (ICP) and particularly also the MIP can advantageously be used as atomizers and ion sources for ultrasensitive elemental MS detection for GC [GC/ICP/MS and GC/microwave-induced plasma mass spectrometry (MIPMS)]. To overcome the pressure difference between the plasma source operated at over-pressure and large gas flows and the mass spectrometer which in most cases is a simple low-resolution quadrupole mass analyzer operated at high vacuum, a special interface is required. This consists of a flexible, heated transfer line through which the analytes are introduced into the plasma torch. In the Ar plasma of the ICP, the analytes are efficiently atomized and ionized. These ions are sampled through a two-stage skimmer into the vacuum of the mass analyzer and detected. The advantages of plasma MS detection are the extremely low detection limits that can be achieved (down to the 50–100 fg range), the simultaneous multielement detection ability and the ability to measure isotopic ratios. In practice, the MIP offers significant advantages over the ICP as an ionization source owing to the lower operating power and supporting gas requirements. Additionally, He has a higher ionization potential than Ar, which increases the sensitivity of detection. Finally, spectral interferences through the formation of cluster ions are less pronounced with He. However, owing to the wider availability of ICPMS, the GC/ICPMS set-up is more popular. Typical applications which benefit from the ultratrace sensitivity of ICPMS detection are in the field of speciation analysis (Figure 26).

Trihalomethanes (THMs) are considered to be the major by-products found in water after the chlorination process. They mainly consist of chloroform (CHCl₃), bromodichloromethane (CHBrCl₂), dibromochloromethane (CHBr₂Cl) and bromoform (CHBr₃). Their content in drinking water is regulated and the maximum contaminant level (MCL) of 100 µg L⁻¹ established in 1979 by the United States Environmental Protection Agency (USEPA) for total THMs, based on a running annual average, still prevails and has been adopted in many other countries. In this article, we describe the four major analytical techniques routinely used for THM analysis. All of these analytical techniques use gas chromatography (GC) with a halogen-specific detector such as the electron capture detector (ECD), electrolyte conductivity detector (ELCD) or mass spectrometry (MS). With high-efficiency capillary columns now commercially available and the high sensitivity of the ECD, all these techniques have detection limits (DLs) at or below 0.1 µg L⁻¹ for each of the four THMs, which is more than adequate for drinking water or beverage applications.

The four analytical approaches differ by the way the THMs are introduced into the chromatographic column. Direct aqueous injection (DAI), where the sample is directly injected into the GC column, is fast and simple. It does not require any other piece of equipment than the gas chromatograph itself. However, since everything in the sample is injected in the column, it is limited to relatively clean matrices. It is generally used as a screening technique when a limited number of samples are analyzed. The second method uses liquid–liquid extraction (LLE) of the THMs with an organic solvent, usually pentane, which is then injected into the GC column. The extraction step offers the possibility of concentrating the THMs from a large-volume sample and isolates them from inorganic salts. However, LLE is by far the most time-consuming procedure and is not well suited for routine analysis of a large number of samples. The last two methods take advantage of the high volatility of the THMs to isolate and concentrate them in the gas phase. In the headspace (HS) technique, the aqueous sample is heated in a sealed vial and an equilibrium is reached between the THMs present in the water and the HS above, from which an aliquot is injected into the GC column. It is simple to use and easily automated. The sensitivity is limited by the partition coefficient of each species between the liquid and gas phases and the size of the gas aliquot injected into the GC column. The DL has been decreased to 1 ng L⁻¹ by use of a long transfer time to the gas chromatograph and cryogenic trapping in the very first portion of the GC column. Finally, in the purge-and-trap (PT) technique, the THMs are purged out of the sample by an inert gas and concentrated on a solid sorbent, thermally desorbed and injected into the GC column. With a purge efficiency close to 100% for these volatile compounds, all the molecules present in a relatively large water sample (typically 5–25 mL) are injected into the GC column. It is the most sensitive of the four analytical methods and a DL...
below the 1 ng L$^{-1}$ level has been achieved with cryogenic focusing at the column head.

## 1 INTRODUCTION

In 1974, Rook$^1$ in The Netherlands and Bellar et al.$^2$ in the USA reported the presence of THMs in chlorinated drinking water. Since then, it has been demonstrated that the chlorination process used to disinfect natural water is indeed responsible for the formation of these halogenated organic compounds. It is generally believed that the THMs represent the main group of organohalogenated organic compounds. It is generally believed that water is indeed responsible for the formation of these compounds formed during chlorination of water. Koch and Krasner$^3$ estimated that among organohalogen compounds found in chlorinated drinking water. By definition, THMs are organic compounds that contain one carbon, one hydrogen, and three halogen atoms. They are formed by the classical haloformal reaction of chlorine with humic and fulvic acids present in natural waters. Bunn et al.$^5$ have shown under laboratory conditions that bromine- and iodine-containing THMs are produced because bromide and iodide are oxidized by chlorine into reactive species, which in turn react with humic and fulvic acids in the same way as chlorine. Even though there is still some controversy about the real health risk and the acceptable level of THMs in drinking water, the MCL of 100 µg L$^{-1}$, with a median value of the order of 30–40 µg L$^{-1}$. In all of these studies, chloroform is always the predominant species. Other references worth mentioning are those of a group of Canadian workers at the Department of Health, who showed that the level of THMs produced is greatly dependent on the source and the quality of the raw water. They established a correlation between the total THM level and the total organic content (TOC) or chlorine demand, and also the pH of the raw water. This correlation can explain the wide range of THM concentrations and the seasonal dependence shown in their studies. Also, the highest values were generally observed in treated surface water and the lowest in the treated groundwater. In their most recent paper, they also observed that the level of THMs increased from the treatment plant into the distribution system, probably because of extended reactions between chlorine and the THM precursors remaining in the water. This was also mentioned in a paper by Koukouraki et al.$^6$.

Several studies have been conducted to assess the potential health risk of long-term exposure to the THMs and other chlorination by-products in drinking water. It has been difficult to obtain conclusive data but the possibility of a causal relationship for rectal cancer and, to a lesser extent, for bladder and colon cancer have been mentioned.$^7$ It has been also reported that cancer of the liver and kidney developed in rats and mice that ate food and drank for a long time water in which a small amount of chloroform was present.$^8$ Even though there is still some controversy about the real health risk and the acceptable level of THMs in drinking water, the MCL of 100 µg L$^{-1}$ established in 1979 by the USEPA$^9$ for total trihalomethanes (THM), based on a running annual average, still prevails and has been adopted in other countries.$^{10,11}$ However, a lower MCL of 80 µg L$^{-1}$ has recently been proposed in USA in the Disinfectants–Disinfection By-products Rule$^{12}$ and a Commission of the European Union suggested levels of 40 µg L$^{-1}$ for CHCl$_3$ and 15 µg L$^{-1}$ for CHBrCl$_2$.$^{13}$

With more data on the long-term risk of THMs and other disinfection by-products, and the evolution of water treatments, it is expected that the MCL could be lowered even further, which justifies the need for very sensitive analytical techniques.

In addition to drinking water, the analysis of THMs has been reported in other types of water and aqueous media. Among them, we should mention the beverage industry,\textsuperscript{(22)} seawater,\textsuperscript{(23,24)} aquatic recreational and therapeutic facilities\textsuperscript{(24–26)} and the power industry.\textsuperscript{(27,28)} In this last field of activities, it has been demonstrated that CHCl\textsubscript{3} rapidly decomposes at the high temperature experienced in thermal power plants to give a stoichiometric amount of chloride.\textsuperscript{(28)} which is a corrosion hazard for the materials used in steam–condensate cycles. In many cases it can easily exceed the safe operational limit, especially in nuclear plants, resulting in limited power production and even complete shutdown.

Although the THMs are regulated as a group in most countries, almost all the methods measure them separately and sum the concentration of the four compounds to obtain the required TTHM value. The volatility of these molecules makes them very good candidates for GC analysis and the high sensitivity and selectivity to halogenated compounds of the ECD, ECLD or MS detector permit one to achieve the very low DLs needed. The analytical approaches presented in this article differ in the way the THMs are introduced into the chromatographic column, and how they are isolated from the matrix and in many cases concentrated. Perhaps the simplest approach is the DAI, used successfully in 1977 by Nicholson et al.\textsuperscript{(29)} and later developed by Grob and Habich\textsuperscript{(30,31)} for capillary columns. This technique, which involves no sample pretreatment and needs no special introduction system, has been widely employed for the rapid screening of THMs. Another simple and conventional way to inject these analytes is after LLE with an organic solvent, usually pentane, proposed in the 1970s by various groups.\textsuperscript{(32–35)} It offers the possibility of concentrating in a small volume of solvent the analyte present in a large sample. Owing to the volatile nature of THMs, another efficient way to isolate them is by gas extraction techniques. Among them, the most popular are HS\textsuperscript{(36)} and PT methods.\textsuperscript{(37)} In the former technique, the aqueous sample is heated in a sealed vial and an equilibrium is reached between the THMs present in the water and the HS above, from which an aliquot is injected into the GC column. In the latter, the THMs are purged out of the sample by an inert gas and concentrated on a solid sorbent, and later thermally desorbed and injected into the GC column.

Two very interesting reviews covering these techniques were published by Oliver\textsuperscript{(17)} in 1989 and Biziuk and Przyjazny\textsuperscript{(11)} in 1996. Both of them cover the wider range of the analysis of volatile organics. In this article, the four analytical approaches will be presented in their specific application to the analysis of THMs in drinking water and other aqueous matrices. After discussing the sampling and preservation of samples, along with standard preparation, each of the major analytical techniques will be described, with their performance, advantages and limitations.

\section{2 STANDARD PREPARATION AND SAMPLE HANDLING}

The analytical techniques used today are very sensitive with DLs in most cases below the micrograms and even at the nanograms per liter level. Reliable results at those levels can only be achieved by observing good laboratory practices and taking very meticulous care at every step of the analytical protocol, from the preparation of the sampling containers to the analysis by GC, and including the preparation of blank water and standards. Although some specific care might be required depending on the analytical technique used, the major precautions to be taken come from the very nature of the THMs and the composition of the aqueous matrix. Therefore, the same standard preparation and sample handling procedures can generally be applied to all of the analytical approaches.

\subsection{2.1 Preparation of Blank Water and Standards}

THMs are not easily removed by commercial water purification systems. Lépine and Archambault\textsuperscript{(38)} have shown that even with a multiple-stage purification system, detectable amounts of THMs are still present. They also showed that some devices such as an ultraviolet (UV) lamp incorporated in the latest version of some commercial systems can even increase the level of THMs, probably by degradation of halogenated intermediates still present in the purified water. The only way they could obtain perfectly clean blanks (no detectable amount of any of the analytes) was by simply purging the water overnight with an inert gas in a 4-L sparger. The sparger was then kept slightly overpressured with helium to prevent atmospheric contamination. The same principle was later used successfully by other groups\textsuperscript{(23,39)} for low trace analysis and is now one of the methods recommended by the USEPA, which also suggests boiling the water for 15 min before purging for 1 h at 90 °C.\textsuperscript{(40)}

Primary standards of the four THMs, mixed or separately, may be purchased commercially at different concentrations between 200 and 2000 mg L\textsuperscript{-1}. They can also be prepared by the user but only ultrapure analytes and methanol should be used. Standards at the thousand milligrams per liter level can be kept for 1 month if stored in glass vials equipped with a Teflon\textsuperscript{™}-face...
silicone septum filled to the brim (with no HS) and kept at 4°C with no direct or intense light. Standards in the micrograms or nanograms per liter range must be prepared daily by successive dilution from the primary standard and also kept in vials with no HS. All glassware used in the preparation of nanograms per liter level standards should be checked with blank water prior to first use, specially marked and never used for other applications or higher concentration standards. These manipulations must be performed in an area known to be free of organic vapors and no halogenated organic solvents should be used or stored in the same laboratory. For quality control, a certified standard reference material can be purchased from the US National Institute of Standards and Technology (NIST).

2.2 Sample Collection and Preservation

The sampling procedure described in this section is based on USEPA methods 502.2, 524.2 and 551.1, which are the three methods prescribed by this organisation for analysis of THMs in treated water. The two major concerns at this step are to avoid contamination and loss of volatile compounds by evaporation. Grab samples are collected in screw-capped glass containers equipped with a Teflon™-faced silicone septum. Alternatively, when headspace gas chromatography (HSGC) is used for analysis, the crimped-cap vials used for this technique can be used to bring the sample to the instrument without any further treatment. In this case, a special sampling procedure is required and will be described in section 5.2. Both the containers and septa are prepared prior to use by washing with detergent and rinsing thoroughly with distilled water or equivalent. They are air dried at room temperature, then placed in a 105°C oven for 1 h, after which they are removed and allowed to cool in an area known to be free of organics. The vials are finally sealed and kept this way until sampling.

If samples, such as chlorinated water, are suspected to contain residual chlorine, a dechlorinating agent should be added into the vial before sampling to inhibit the chlorination reaction during sample storage. Many workers have observed an increase in THM concentration when no preservative was added. The preferred dechlorinating agent according to the USEPA is sodium thiosulfate, but ascorbic acid may also be used, as demonstrated by Norin and Renberg. A 3 mg amount of sodium thiosulfate or 25 mg of ascorbic acid are added per 40 mL of sample, but if chlorine is likely to be present at >5 mg L⁻¹, its concentration should be determined and the same amount of dechlorinating agent added for each additional 5 mg L⁻¹ of residual chlorine. In USEPA method 551.1, which uses an LLE procedure, ammonium chloride (6 mg per 60 mL of sample) is also suggested as a dechlorinating agent. Kawakami et al. successfully used hydrazine sulfate and phosphoric acid to preserve samples for TTHM analysis over a period of 9 days. Badawy observed a small loss in the recovery of THMs in the analysis by HSGC at 60°C when sodium thiosulfate or sodium sulfite was used as dechlorinating agent, presumably because these species can react with an alkyl halide to form an S-alkylthiosulfonate and sulfonic acid. No loss in the recovery of THMs was reported by the author when potassium hexacyanoferrate(II) was used as dechlorinating agent.

At the sampling site, the vials must be filled to the brim, without any HS, to avoid contamination from the atmosphere at the sampling station and loss of analyte from the water before analysis. Care should be taken not to flush the dechlorinating agent and that no air bubbles pass through the sample or are trapped when the vial is sealed. The sample is acidified by adding two drops of 1:1 HCl and the vial is sealed, Teflon™ face down, and mixed for 1 min. The dechlorinating agent should not be mixed with HCl in the vial before sampling. The only exception is for HSGC analysis when the analytical vials are filled at the sampling site. In this case, only the specified amount of sample is introduced in the vial, leaving the required HS above the water (see section 5.2).

It should be noted that:

1. If only THM analysis is to be performed, the acidification step can be omitted if sodium thiosulfate is used as dechlorinating agent. This exception does not apply if ascorbic acid is used for dechlorination.
2. If the sample foams vigorously when HCl is added, the sample should be discarded. Another set of samples should be taken without adding the HCl, marked as “not acidified” and analyzed within 24 h of collection if compounds other than THMs are to be determined.

The samples must be chilled to 4°C and maintained at that temperature until analysis. If proper dechlorination measures have been taken and there is no HS in the vial, samples can be stored for 14 days at 4°C before analysis. If LLE is performed on the sample, the organic extracts should be kept in a freezer (<−10°C) and analyzed within 14 days. The storage area must be free of organic solvent vapors and direct or intense light.

3 DIRECT AQUEOUS INJECTION GAS CHROMATOGRAPHY

The DAI approach is the simplest method of all because it does not require any sample pretreatment or special device for sample introduction into the GC column. It refers to the syringe injection of the water sample directly
into the gas chromatograph, without any extraction or concentration step. Nicholson et al.\(^{29}\) in 1977 were the first to report the determination of THMs in water using the DAI technique. They injected a 9-µL sample into a 2-mm packed column through a hot injector. They found that the application of this technique to chlorinated water lead to concentrations of THMs significantly higher than the gas sparging technique. Different experiments demonstrated that those higher THM values were the result of the formation in the injector of these compounds by thermal degradation of precursors also present in the sample. Therefore, the results they obtained could be categorized as the total potential haloform that can be formed after chlorination rather than the true concentration in the sample. This phenomenon was studied a year later by Pfaender et al.\(^{44}\) who also came to the same conclusion. They showed that a value close to the true THM concentration could be obtained if the sample is injected after a 30-min purge and subtracting this value from the one obtained without purging.

The turning point in the development of the DAI technique was the use by Grob and Habich\(^{30,31}\) in 1983–84 of a cooled injector for on-column injection into a capillary column. The water sample is injected in a cooled portion of the column, avoiding the thermal degradation of THM precursors in the injector. Grob has described in depth the different parameters that affect this mode of injection for aqueous samples.\(^{31}\) Basing their work on his development, many workers have used the DAI technique for rapid screening of THMs alone\(^{20,45}\) or with other halogenated organics\(^{24,46}\) in drinking water.

For other more complex matrices, Kozlowski and Polkowska\(^{47,48}\) used an isolation and enrichment technique called thin-layer headspace (TLHS) with self-generation of liquid sorbent. In this version of TLHS, the water sample is heated and the volatile compounds are extracted from the aqueous sample into the gas phase. They are then transferred by a stream of gas into a cooled thermostated tube where water vapor undergoes condensation along with the analytes. This technique produces an aqueous concentrate which is sufficiently pure to be analyzed by DAI. Polkowska et al.\(^{22}\) successfully applied this technique to the analysis of THMs in commercial beverages, with a DL 10 times lower than that of the DAI technique alone.

A good review of the different aspects of the DAI technique has been published by Turska et al.\(^{49}\)

### 3.1 Instrumentation

As already mentioned, the DAI technique requires a gas chromatograph with a cooled injector. Grob\(^{31}\) pointed out that the best results are obtained with on-column injection, which avoids delayed water elution caused by diffusion and dilution in the injector cavity before the analytes enter the column. Even splitless injection gave much larger peaks than on-column injector. Grab explained this result by the fact that the solubility of the halocarbons is too low for the reconcentration effect to occur in the first portion of the column, which is a key part of this injection mode. As a result, the analytes migrate through the column in a rather large band, resulting in severely broadened peaks.

Column selection is also critical with this injection technique and must fulfill two primary requirements. First, it must elute the water rapidly and completely. This is achieved by nonpolar stationary phases such as methylsilicone. To improve the separation of the analytes, the methylsilicone stationary phase can be modified with small amounts of phenyl or vinyl groups. Second, the volatile analytes need to be sufficiently retained to come out long after the elution of water has ended. The use of the thickest possible stationary phase is the only way to achieve this goal. It provides the necessary strong retention of apolar halocarbons and a high loading capacity, avoiding excessive broadening of the water peak. However, this leads to low efficiency, broad peaks and reduced sensitivity. As a compromise, film thicknesses of 2–5 µm have generally been used for the analysis of THMs by DAI.\(^{20,22,24,45,46}\) The stationary phase should be immobilized through cross-linking and chemical bonding to the column wall to avoid its hydrolysis by the large amount of water injected. Medium- and wide-bore columns (0.28–0.54 mm) are typical, since the injection of a large volume of water could block temporarily the gas flow in a small diameter column. A column length of 25–30 m is also the most often used, which represents a good compromise between resolution and loss in sensitivity through peak broadening.

A retention gap, consisting of a deactivated fused-silica column (1–2 m) is recommended to protect the column from nonvolatile inorganic and organic compounds that might be present in the water sample and that will accumulate at the column inlet and degrade the resolving power of the column. This precolumn can be replaced after a specified number of injections or when performance degradation is observed by broadening of the water peak. The retention gap also serves to narrow the chromatographic bands and permits large-volume injections.

Finally, the ECD is the detector of choice because it combines very high sensitivity and selectivity for halogenated compounds, especially for the THMs which have three halogens per molecule.

### 3.2 Method Parameters

The optimal column temperature for isothermal runs is just above the boiling point of water, at about 103–104 °C,
as recommended by Grob. \textsuperscript{311} At lower temperatures, the elution of water is delayed, resulting in poorer resolution of the lighter halocarbons. At higher temperatures, peak splitting was observed which was more severe with increasing molecular weight, but this phenomenon could not be explained. After the water has eluted from the column, temperature programming can be used for the separation of heavier compounds. The ECD is usually operated at high temperature (300–350 °C) and a makeup gas flow rate of ca. 25–50 mL min\textsuperscript{-1}. This allows for the fast elution of water through the detector cell and a narrower water band.

The calibration of the GC signal is easily performed by external standardization, injecting composite standards prepared in water or in any other suitable solvent. A recovery test should be performed with a fortified sample to check for matrix effects, specially with complex aqueous matrices.

### 3.3 Analytical Performance

The analytical performance obtained by different groups who have reported the use of DAI for the analysis of THMs in water are summarized in Table 2 along with their chromatographic conditions. The best results were obtained by an injection of 1–2 μL of water sample into a cold on-column injector or a SPI, a 26–30 m × 0.32 mm ID capillary column with a 5-μm film thickness and an ECD. With this configuration, the DL is typically between 0.01 and 0.06 μg L\textsuperscript{-1}. A typical chromatogram obtained under these conditions by Carmichael and Holmes \textsuperscript{45} is shown in Figure 1, along with the analysis of a community drinking-water sample. The DLs obtained with a 0.32 mm ID column are an order of magnitude lower than those reported by Temmerman and Quaghebeur \textsuperscript{20} using a megabore column (0.53 mm ID) and similar other conditions. Pyle and Gurka \textsuperscript{46} obtained even higher DLs using a megabore column but with an ion-trap mass spectrometer, partly because they could not obtain reliable results using injection volumes greater than 0.2 μL, which is 10 times less than the volume injected by the other groups. Finally, the precision reported by the different groups is generally fairly good, with <5% RSD at the 10–20 μg L\textsuperscript{-1} level.

### 3.4 Advantages and Limitations

The main advantage of DAI is obviously its simplicity. It does not require any piece of equipment other than a gas chromatograph equipped with a cooled injector. Moreover, since no pretreatment or preconcentration step is performed, it eliminates the sometimes laborious step of sample preparation and the risk of either contamination or loss of very volatile analytes prior to the analysis. It is a fast analytical method that can be used for rapid THM screening and quality control in a water treatment plant and can be easily automated with the addition of an autosampler to the chromatograph.

The problem of stationary phase stability with regard to the large volume of water injected, encountered in the early development stage of the technique, has been

resolved by the advent of modern capillary columns with chemical bonding and cross-linking of the coating. Another problem experienced was the deterioration of column performance due to the deposition at the head of the column of nonvolatile inorganic and organic compounds present in the sample. This can be overcome by the use of a precolumn, which can be easily replaced after a preset number of runs. However, other compounds can nevertheless cause some problems and DAI should be used mainly for relatively clean samples, such as finished chlorinated water. The other fundamental drawback of the technique is the very small amount of sample that can be introduced, which limits its sensitivity. For these reasons, an enrichment and/or isolation technique, such as the previously mentioned TLHS, has to be performed in conjunction with the DAI technique for analyzing low THM concentrations and very complex matrices.

4 LIQUID–LIQUID EXTRACTION GAS CHROMATOGRAPHY

LLE is one of the oldest methods for the isolation of organic compounds from aqueous samples. It has often been used in the past as a reference to validate other analytical approaches and is still one of the methods recommended for THM determination in drinking water by the USEPA. It is based on the principle that THMs, as other organic compounds, tend to partition preferentially from water into an organic solvent. The equilibrium between the two phases can be written mathematically as Equation (1):

$$K_d = \frac{C_s}{C_w}$$  \hspace{1cm} (1)

where $K_d$ is the distribution coefficient and $C_s$ and $C_w$ are the concentration of the analyte in the solvent and in the water sample, respectively. The extraction efficiency of the solvent for a given analyte is then represented by Equation (2):

$$E = \frac{100K_d}{K_d + (V_s/V_w)}$$  \hspace{1cm} (2)

where $E$, the extraction efficiency, is expressed in percent and $V_s$ and $V_w$ are the volume of the solvent and the water sample, respectively. We can see from this equation that an efficiency close to 100% is obtained only if $K_d$ is high and the ratio $V_s/V_w$ is low. However, the latter situation is not desirable because it would imply that the volume of solvent is much greater than that of the water sample, which would dilute the analyte. In contrast, to obtain the increased sensitivity by concentrating the analyte in a smaller volume of solvent, the volume...
The solvent used for extraction has to fulfill two criteria: it has to be immiscible with water and the THMs must be considerably more soluble in it than in water (high $K_d$). Many solvents have been used by different research groups, the most common being pentane. It is preferred by most investigators. The USEPA, in its method 551.1, uses methyl tert-butyl ether (MTBE) but proposes pentane as an alternative.

### 4.1 Instrumentation

As for the DAI technique, the only piece of equipment required with LLE is a gas chromatograph. The best results have been obtained with an on-column or splitless injection and an ECD. The injection volume of the extract is generally between 0.5 and 2 µL. The choice of the column and the temperature program will depend on the presence of interfering species extracted from the sample along with the THMs. In the most recent papers, medium- or narrow-bore capillary columns (0.25–0.32 mm ID) with a standard film thickness (~1 µm) have been used to obtain high resolution and narrow peaks.

The use of an ECD is highly recommended, because of its high selectivity for halogenated compounds and its relatively pure and the few researchers who have systematically compared these different solvents with the same extraction procedure concluded that they give comparable results, and that the choice of a particular solvent rests on the preference of the analyst.
high sensitivity for the THMs. Also, the low response of this detector to the alkane solvents generally used in LLE is a net advantage of this detector.

### 4.2 Method Parameters

A volumetric flask has been suggested by some workers\(^ {34,41} \) to perform the extraction. With the water sample to the mark, the required amount of solvent is added and the flask shaken manually. As a result of the narrow neck, the organic extract is easily removed from the top of the aqueous sample since all the suggested solvents have densities lower than that of water. Another convenient and more efficient way to perform the extraction, especially with many samples, is in septum-sealed vials on a mechanical or orbital shaker. The sampling vials in which the samples are stored can even be used for the extraction by removing a certain amount of sample and adding the required amount of solvent. The exact volume of sample extracted is determined by subtracting the weight of the empty vial from the weight with the sample before adding the solvent.

The determination is generally performed by extracting aqueous composite standards with the same procedure as for the samples. These standards must be prepared by spiking a known amount of the analytes directly in the extraction vessel containing blank water. This is necessary to avoid loss of the volatile analytes during transfer of the standard solution. The extraction efficiency should be

---

**Figure 2** Analysis of organohalides by LLEGC/ECD. (a) Standard mixture of 0.1 µg L\(^{-1}\) each in pentane, 2 mL equilibrated with 50 mL of water; (b) organohalides from Lake Constance water supply, sampled in Tübingen, Germany. checked by extracting fortified samples, especially with complex aqueous matrices or whenever a matrix effect is suspected. A surrogate analyte, not present in the matrix, could also be added to the extraction vessel to monitor the method performance with each sample.

4.3 Analytical Performance

Table 3 presents the extraction efficiencies and the DLs and precisions reported by different analytical groups with the LLE technique. Most of them used pentane as the extraction solvent. The extraction efficiencies are satisfactory, with values between 70 and 90%. The DLs lie in the range 0.1–1 µg L⁻¹. The precision is fairly good with values generally between 2 and 6%. Figure 2(a) and (b) show a typical chromatogram of a pentane extract of a municipal water supply obtained with a 25 m × 0.2 mm ID column along with one of the calibration standards. The 10-min run is sufficient to separate the four THMs along with five other organohalide compounds. The best results are those presented in the 1995 edition of USEPA method 551.1, which uses on-column or splitless injection in a narrow-bore capillary column. Their DL is at least one order of magnitude lower than that published earlier, with very good precision. In their method, NaCl is also added to the sample to increase the extraction efficiency. However, it has been noted recently that elevated recoveries of brominated THMs (by synthesis) have been observed in the NaCl. For that reason, the authors strongly recommend the use of Na₂SO₃ as a replacement for NaCl.

4.4 Advantages and Limitations

The major advantage of the LLE method is that, as in the DAI approach, it does not need any apparatus other than a gas chromatograph. In addition, it eliminates the problems associated with the injection of a large quantity of water into the GC column and also isolates the analytes from the inorganic impurities present in some matrices, although organic compounds soluble in the extraction solvent might interfere. It has proven effective in concentrating the THMs from a large sample into a small volume of solvent for higher sensitivities.

However, this technique implies a tedious extraction step which cannot be completely automated and requires the intervention of the analyst during the process. It also involves the use of expensive, high-purity solvents, which might be toxic to handle and represent a hazardous waste. The risk of contamination or solvent losses by evaporation during the extraction is also very high and meticulous care in the extraction process, together with good quality control of the process, are mandatory. Finally, the formation of emulsions with certain matrices is yet another problem with this technique.

5 HEADSPACE GAS CHROMATOGRAPHY

The volatility of the THMs and their tendency to partition into the gas phase over aqueous solutions have been used by some analysts to extract these compounds in water samples. The HS analysis technique refers to the determination of the analyte concentration in the gaseous phase being in thermodynamic equilibrium with the sample. Although some authors have used the terms “dynamic HS” for techniques where the gas passes continuously over the surface of the water sample or bubbles through the liquid (which will be discussed in the next section), the word HS will be strictly applied in this article to designate the sampling of a static gaseous phase in equilibrium with the sample in a sealed container, as is the practice in the literature.

A comprehensive book by Kolb and Ettre re-edited in 1997 describes in detail the theoretical background and practical aspects of HSGC. In similar terms to those for LLE, the distribution of the analyte between water and gas phase at a given temperature is governed by the partition coefficient $K_p$, which is a fundamental parameter of an analyte under given conditions and is generally defined in the HS literature by Equation (3):

$$K_p = \frac{C_w}{C_g}$$

where $C_w$ and $C_g$ represent the concentration of the analyte at equilibrium in the water and gas phases, respectively. Knowing that $C = W/V$, a mass balance of the system can be expressed according to Equation (4):

$$C_0 V_w = C_g V_g + C_w V_w = C_g V_g + K_p C_g V_w$$

or Equation (5):

$$C_0 = C_g \left( K_p + \frac{V_g}{V_w} \right)$$

where $C_0$ is the original concentration of the analyte in the aqueous sample and $V_g$ and $V_w$ are the volume of the gas and water phases, respectively. Introducing the phase ratio $\beta$, given by Equation (6):

$$\beta = \frac{V_g}{V_w}$$

Equation (5) becomes Equation (7)

$$C_0 = C_g (K_p + \beta)$$

In a given system and under a given set of conditions, both $K_p$ and $\beta$ are constant, hence the original concentration in the sample $C_0$ is proportional to the concentration in the
gas phase at equilibrium, $C_g$, which can be determined by injecting an aliquot of the gas phase into the gas chromatograph. This is the basis of quantitative HSGC.

The use of the HS technique for THM analysis was reported by Kaiser and Oliver$^{36}$ in 1976, using a 60-mL separating funnel immersed in a thermostated water bath and filled with the sample to leave an HS of 2 mL, which was sampled with a gas-tight syringe. A similar set-up was also used by Piet et al.$^{58}$ with a 600-mL sample and a 100-mL HS. However, a more convenient way to perform HS sampling is in a septum-sealed vial, where the HS can either be sampled manually with a gas-tight syringe or transferred directly to the GC column. Kolb et al.$^{59}$ described the use of an automatic electropneumatic sampling system where the vial containing the sample is pressurized before the HS is injected into the GC column through a standard split injector. This electronically controlled pneumatic dosing system gave a typical reproducibility of $1 \pm 1.5\%$ and could be automated for several vials. Otson,$^{60}$ a few years later, used a commercial GC autosampler with standard 2-mL vials for performing HSGC of THMs analysis at ambient temperature. Other more recent papers on THM analysis by HS have compared the results obtained with other techniques such as LLE$^{64,61,62}$ or PT.$^{63,64}$ They showed comparable analytical results in terms of accuracy and precision. The sensitivity was similar to that of LLE but lower than that of the PT technique.

Finally, a variation of HS sampling worth mentioning is a technique called solid-phase microextraction (SPME), proposed by Zhang and Pawliszyn.$^{65,66}$ which uses a fused-silica fiber coated with a suitable stationary phase contained inside the needle of a special syringe. During SPME, the volatile compounds concentrate on the fiber, which is lowered into the HS of the vial for a predetermined length of time. Once sampling is completed, the fiber is withdrawn into the syringe needle and immediately inserted into the GC injector, where the analytes are thermally desorbed and injected into the GC column. Although very good results have been obtained with DLs at the $0.01 \mu g L^{-1}$ level and precision $<5\%$,$^{66,67}$ more data are needed on the ruggedness of the technique.

### 5.1 Instrumentation

Today, most chromatographic companies are selling dedicated automatic HS samplers with precise control of the equilibration time and temperature and the pressure in the vial prior to the injection. Some also incorporate additional features, such as vial vibration, which shorten the equilibration time for certain viscous samples. There are three basic types of HS sampling systems: gas-tight syringe, time-controlled balanced pressure and the pressure/loop system. The first case is the simplest of all, where an aliquot of the gas phase is taken with a gas-tight syringe and subsequently injected through the septum of a standard injection port. It can be performed manually or with an automated sampler. The major problem of this approach is that the pressure and the temperature of the sample, and hence the amount injected, are not controlled and actually change in the syringe during the transfer because of expansion through the needle. This problem can be partly overcome in manual injection by the use of a Luer-lock valve. Automated systems usually have a heated syringe but do not have the possibility of locking the pressure. An interesting approach described by Kold and Ettre$^{67}$ is the combination of a gas syringe and a heated gas sampling valve. The syringe is used to pull the gas sample through the sample loop of a six-port sampling valve, which is then actuated to inject the aliquot into the column. The amount injected is determined by the temperature and pressure of the sample in the sampling loop, its volume being fixed by the loop dimension.

The other two instrumental approaches are schematized in Figure 3(a) and (b). In the balanced-pressure system, the vial is pressurized by the carrier gas, after equilibrium has been reached, to a pressure equal to the inlet pressure of the column. Next, the carrier gas supply is interrupted by closing valve V1, and the pressurized HS in the vial expands to reach the column. Since both the pressure and time for this operation are set parameters, the amount of sample introduced into the column can be accurately controlled. With this system, it is possible to transfer a large HS volume to the GC column to increase the sensitivity. However, cryogenic refocusing of the analytes at the head of the column is necessary to avoid peak broadening. Large amounts of water vapor would also be transferred and would have to be removed in order to avoid blockage of the column by ice. Kolb et al.$^{68}$ showed a set-up incorporating an LiCl trap to remove most of the water before the cooled portion of the column. Finally, a separate gas supply can be used for the pressurization, thus allowing balanced-pressure or increased-pressure injection (above the column inlet pressure) to be performed.

The pressure/loop system (Figure 3b) also starts by pressurizing the gas phase in the vial, usually with the same inert gas as the one used as carrier in the gas chromatograph. The HS is later vented to the atmosphere through the injection loop which is then actuated to put the loop in line with the gas chromatograph and inject its content into the analytical column. The pressure in the loop can be adjusted from atmospheric to the pressurized level by proper setting of the backpressure regulator. With the pressure/loop system, large-volume injection with cryogenic refocusing cannot be performed as easily as with balanced-pressure systems, but could be accomplished by
the multiple-HS-injection technique, repetitive injection from a single vial or from multiple vials.

The HS approach, which introduces the sample already in a gaseous state, does not cause any constraint on the choice of the GC column. Unless a very high resolution is required because volatiles co-eluting with the THMs are present in the matrix, a medium-to-wide-bore capillary column (0.32–0.53 mm ID) with a slightly polar stationary phase (DB5 or equivalent) is recommended. The high capacity of these columns can accommodate large-volume injection and the higher gas flow facilitates the transfer of the gas aliquot from the HS unit, giving faster analysis. Finally, the high sensitivity of the ECD makes it the best candidate for THM detection.

5.2 Method Parameters

One special feature of HS analysis is that the vials used for analysis can be filled at the collection site. The vials should first be sealed and flushed with an inert gas in order to avoid atmospheric contamination at the sampling site. The water is sampled with a syringe and introduced into the vial through the septum. A second needle is required when the vial is being filled up to release excess pressure. The second needle is left in place one or two seconds after fill-up in order to equilibrate the HS to atmospheric pressure. This is necessary to ensure that the same pressure is present in all the sample vials and in those containing the standard solutions, which will normally be filled at the laboratory under atmospheric pressure. The amount of sample introduced into the vial can be determined by noting the volume on the syringe, or more precisely by the variation in weight of the vial before and after sampling.

In the HS systems, the pressure, temperature and sequence timing must be precisely set in order to obtain reproducible results. Even though only a few seconds would be enough to pressurize the vial, a longer pressurization time (1–3 min) is recommended to achieve...
proper homogenization of the HS. The second variable adjustable by the operator is the temperature of the six-port valve and the transfer lines from the vial to the valve and from the valve to the gas chromatograph. It should be high enough to prevent any condensation of the sample, but not so high that the septum is burned by a hot needle or that thermal degradation and/or oxidation of sensitive analytes occur. Usually, the temperature is set at or slightly above the thermostating temperature. Finally, the timing sequence and especially the transfer time in a balanced-pressure system need to be precisely controlled in order to obtain reproducible amounts of analytes injected into the column. This is well achieved by the commercial HS instruments now available.

It can be seen in Equation (7) that for a given \( C_0 \), the highest \( C_g \) and consequently the highest sensitivity will be obtained by minimizing both \( K_p \) and \( \beta \). However, since improvement in sensitivity is directly related to the sum of these two parameters, the impact of working on one of them will depend on their respective absolute values. For example, since for the THMs \( K_p \gg \beta \), moving towards lower \( K_p \) values will have a greater impact than changing \( \beta \). Also, the latter parameter can only be reduced to a certain extent because there must be enough HS volume available for transfer into the column (typical volumes injected are 0.5–2 mL). One also needs enough space to ensure that the needle of the HS sampling system will not get into the liquid phase. For these reasons, in a typical 22-mL vial, the sample usually does not exceed about 80% of the vial volume, corresponding to a minimum phase ratio of 0.25. Since the THMs have different values, minimizing \( K_p \) will have a greater impact on CHCl\(_3\) than CHBr\(_3\) (\( K_p = 2.3 \) and 12.8, respectively, at 65 °C).\(^{69}\)

It can be derived from Henry’s law that \( K_p \) is inversely proportional to the vapor pressure and the activity coefficient of a particular analyte.\(^{67}\) Therefore, increasing the temperature, and consequently the vapor pressure, will decrease \( K_p \) and enhance the sensitivity. Kaiser and Oliver\(^{66}\) observed an exponential sensitivity increase for the CHCl\(_3\) peak from 30 to 90 °C, with a 10-fold increase between these two temperatures. However, they chose to work at 70 °C to minimize the amount of

water vapor transferred with the analyte, which adversely affects the reproducibility of the results. It should be noted that the influence of temperature is an analyte-specific function and must be evaluated separately for each case. Another way to minimize $K_p$ is to increase the activity coefficient of the analyte by the addition of an electrolyte to the sample, commonly called the “salting-out” technique. This effect has been mentioned in a few papers\(^{57,63,64}\) for the THMs and increases inversely with their respective solubility, the more pronounced sensitivity improvement being with CHBr$_3$. However, it should be mentioned that high salt concentrations (20–50%) are needed to obtain a significant enhancement in sensitivity, which can typically range from one to five times the signal without salt addition. Salting-out also influences the linear range of various compounds and the technique should be investigated for each analyte before being incorporated into routine quantitative analysis.

The determination is generally performed by analyzing aqueous composite standards. To avoid loss of the volatile analytes during transfer, these standard solutions are best prepared by spiking a known amount of the analytes directly in the HS vial containing blank water and prepared with exactly the same procedure as for the samples. It is especially important to have the same volume ratio and initial pressure in the vial for the standards and the samples. Also, since the matrix composition can affect $K_p$, the recovery of the different analytes obtained with the spiked standards should be compared with those for fortified samples, especially with complex aqueous matrices containing a high salt content. A surrogate analyte, not present in the sample, could also be added to detect changes in matrix composition that could affect $K_p$.  

5.3 Analytical Performance

The analytical performance reported by different groups who have used HS for the analysis of THMs are summarized in Table 4. The precision is satisfactory and is usually <10%. The DL is generally between 0.1 and 1 µg L$^{-1}$, which is comparable to the DAI or LLE technique. Onodera et al.\(^{61}\) compared, on the same chromatographic system, HS with LLE and obtained
The concentration of the THMs, except for CHBr₃ which cryofocusing in a 0.32 mm ID capillary column (Figure 4). A chromatogram of mineral water analysis obtained with injection into the GC column. Kolb and Ettre(57) showed a chromatogram of mineral water analysis obtained with cryofocusing in a 0.32 mm ID capillary column (Figure 4). The concentration of the THMs, except for CHBr₃ which was not quantified, were between 7 and 11 ng L⁻¹, and judging by the S/Ns of the peaks in the chromatogram, the DL can be estimated to be 1 ng L⁻¹. Finally, the linearity was shown by Castello et al.(54) to extend over two to three orders of magnitude, thus simplifying the calibration step for different samples.

5.4 Advantages and Limitations

The major advantage of the HSGC technique is its simplicity of operation. The operator only has to put the vials in the sampler and start the run. With the commercial equipment available, the analysis of many samples can be automated, which makes it possible to run the system unattended and to perform the analysis of a large number of samples around the clock. Also, the fact that extraction is performed in disposable containers simplifies the preparation and cleanup for a series of analyses and minimizes the risk of contamination or carryover between samples. Finally, the isolation of the THMs from most of the water and the inorganic or nonvolatile organic compounds that might be present in the sample makes the chromatography simpler than DAI or LLE.

The only disadvantage of HS is that it requires an additional piece of equipment interfaced to the gas chromatograph to perform the HS extraction. Also, the time required to reach equilibrium adds to the chromatography run time for a particular sample. However, modern equipment can perform equilibration of the next sample concurrently with the chromatographic run. The total analysis time per sample is thus the longer of the equilibration time and the GC run time.

6 PURGE-AND-TRAP GAS CHROMATOGRAPHY

As with the HS technique, PT takes advantage of the high volatility of the THMs to isolate these compounds from the aqueous matrix into a gas phase. Both techniques are, in essence, a gas extraction, where the amount of each compound in the gas phase is dependent on its vapor pressure and its solubility in the sample (Kᵥ).

However, instead of isolating a portion of the analytes in a closed HS above the sample, purging the sample constantly sweeps the extracted compounds away to a trap, where they accumulate. Under these circumstances there is no migration of components from the vapor back to the liquid phase. This means that the partial pressure of any individual component above the sample at any time is essentially zero, which encourages an even greater migration of the volatiles into the vapor phase. The amount of analyte extracted from the sample is no longer limited to the equilibrium concentration given by the partition coefficient and, in theory, the totality of a particular volatile compound could be extracted. This can be performed by simply passing a stream of inert gas above the sample, but a much more efficient way of doing it is by passing the gas in the form of tiny bubbles through the liquid phase, thus considerably increasing the interface between the two phases.

The technique was first developed in 1974 by Bellar and Lichtenberg, (37) who designed a purging device made of a specially shaped glass tube equipped at the base with a medium-porosity glass frit, which allowed finely divided gas bubbles to pass through the sample. They showed that slightly soluble (<2% soluble) volatile compounds, such as CHCl₃, could be quantitatively extracted from a 5-mL water sample using <150 mL of nitrogen. The extracted volatiles passed through a trap made of a short section of stainless-steel tubing packed with an adsorptive material such as chromatographic-grade porous polymers (Tenax®, Chromosorb®, etc.), silica gel or molecular sieve. The trapped compounds were thermally desorbed and transferred to the GC column for analysis. The trap-and-release process was quantitative for CHCl₃ and other compounds having a high retention affinity for the adsorbent used, while water vapor passed through the sorbent bed with no adsorption when porous polymer was used. With a packed GC column and flame ionization detection (FID), they claimed a DL of approximately 0.5 µg L⁻¹ for many compounds. THM analysis by the PT approach, along with other halogenated organic compounds, was published by the same authors in 1981 as a USEPA method.(70)

Dressman et al.(52) used ECD and compared the PT with the LLE approach for the analysis of THMs in water. They obtained comparable results and the DLs for all four THMs were between 0.1 and 0.2 µg L⁻¹. Other groups have tried to simplify the technique by eliminating the adsorbent trap and adsorbing the purged organics at the beginning of a packed GC column at close to ambient temperature. (71,72) Their analytical performances were essentially comparable in terms of sensitivity and precision to those of Dressman et al.

The advent of capillary columns with sharper peaks and consequently higher signals permitted the sensitivity of
ENVIRONMENT: WATER AND WASTE

GC analysis to be improved significantly. However, since the carrier flow rate is considerably reduced with these columns, the desorption process on the PT trap is slower and some sort of analyte refocusing at the head of the column, generally by cryogenic trapping, must be used to prevent peak broadening and avoid losing the benefit of the capillary column. Trussell et al. with MS detection reported DLs “at the low nanograms per liter” level without giving specific numbers, but the precision even at the micrograms per liter level was only fair. The best results were published by Lépine and Archambault, with DLs of 0.01–0.05 ng L\(^{-1}\) and precisions of 2.7–4.5% at the 1 ng L\(^{-1}\) level. They used ECD with liquid-nitrogen cryotrapping in the first centimeters of a 0.53 mm ID column. They also emphasized the need for special attention to the blank and standard preparation, along with sample handling, which are all critical parts of the analytical protocol at such low concentrations. Connan et al. later used a similar set-up to measure THMs and other halogenated organics at the nanograms per liter level in a 30-mL seawater sample. Another study worth mentioning is that of Zygmunt, who reported a DL of 1 ng L\(^{-1}\) and good precision by using a sorbent microtrap instead of cryogenic focusing at the head of the analytical GC column. Finally, Wang et al. used a specially designed sparger and a portable gas chromatograph for monitoring THMs in continuously flowing tap water, with a new analysis performed every 15 min.

6.1 Instrumentation

Commercial units are now available to perform PT analysis and a schematic diagram of a typical instrumental set-up is shown in Figure 5(a) and (b). The PT module is composed of a glass sparger, an adsorption trap with a heating jacket and a six-port valve. Many trap compositions are sold commercially for different applications but, if only THMs are being analyzed, a Tenax\(^{®}\) trap is the most often used because this material does not adsorb water and has good adsorption/desorption characteristics for these analytes. The six-port valve and the transfer lines from the trap to the valve and from the valve to the gas chromatograph are heated to avoid condensation. The transfer line from the PT unit to the gas chromatograph is ideally connected directly to the analytical column with a zero-dead-volume (ZDV) connector. A cryofocusing unit is optional but highly recommended when working with capillary columns, especially medium- and narrow-bore columns. Alternatively, the analyte refocusing can be performed by cooling the GC oven to subambient temperature if the chromatograph has this option.

There are no special requirements for the GC column and its choice will be dictated by the type of matrix analyzed in order to obtain adequate resolution of the THMs from interferents. However, larger bore columns allow a higher gas flow, which reduces the desorption time and the transfer of the analytes from the trap to the gas chromatograph. Nonpolar or slightly polar phases such as methylsilicone or 5% phenyl–methylsilicone are the most often mentioned in the literature. Many detectors can be used, but most of the work published has been performed with an ECD because of its great sensitivity and selectivity for halogenated compounds, along with its wide dynamic range.

6.2 Method Parameters

The following procedure is performed in a PT injection analysis. In the purge mode (Figure 5a), the purge gas flows through the sparger and carries the analytes to the trap after which a dry purge of few minutes, where the purge gas flows directly through the trap, may be performed. The latter step is recommended to remove excess water physically adsorbed on the trap. Then the trap is heated and the six-port valve actuated (Figure 5b) so the trap is backflushed by the GC carrier gas to transfer the analytes to the GC column. After the desorption is

![Figure 5 Instrumental set-up involved in PTGC/ECD. (a) Purge mode; (b) desorb and injection mode. [Reprinted with permission from L. Lépine, J.-F. Archambault, Anal. Chem., 64, 810–814 (1992). Copyright 1992, American Chemical Society.]](image-url)
complete, the injection is made by increasing abruptly the temperature of the cryogenic unit or the GC oven. The sorbent trap is also heated at a higher temperature between runs to clean it from any remaining compounds and avoid carryover.

The parameters that could be optimized to obtain the best performance of a PT set-up are the temperature of the sparging unit, the sample volume and the purge-gas volume (time × flow rate). For the former parameter, heating the sample would result in more water being transferred with the purged analytes and give less reproducible results. It might also lead to difficulties in the subsequent GC analysis. This is why most studies are performed at room temperature. Using a large sample volume could improve the response but is often limited by the volume of the sparger and would require a long

purge time and large purge-gas volume, which could lead to breakthrough of the more volatile compounds from the sorption trap before the purge is completed. Typically, a 5–25-mL sample is used on most commercial units. Hence the only practical parameters left for optimization are the purge time and flow rate.

Lépine and Archambault\textsuperscript{38} optimized the purge time for THM analysis and found that with a flow of 40 mL min\textsuperscript{-1}, CHCl\textsubscript{3} is purged completely in only a few minutes whereas for CHBr\textsubscript{3}, the least volatile of the group, the purge efficiency is greatly improved with a longer purging time but tends to reach a plateau after 8 min. The purge efficiencies obtained at 8 min for CHCl\textsubscript{3}, CHBrCl\textsubscript{2}, CHBr\textsubscript{2}Cl and CHBr\textsubscript{3} are 100, 99.7, 95.2 and 78.6\%, respectively. These values are satisfactory and increasing the purge time only marginally improves the efficiency for CHBr\textsubscript{3} and might also cause the breakthrough of CHCl\textsubscript{3} (the most volatile of the THMs) from the sorption trap. For the other parameters, they basically used standard values recommended by the manufacturer. A typical chromatogram obtained under these conditions is presented in Figure 6(a) and (b) for a 100 ng L\textsuperscript{-1} standard, along with an analysis of a river-water sample showing concentrations between 1 and 23 ng L\textsuperscript{-1} for the four THMs. Finally, for working at very low concentrations, a special working procedure should be followed. The Tenax\textsuperscript{6} trap must be conditioned by a 15-min bake every morning, followed by a blank run to verify the cleanliness of the system. In addition, the sparger is purged for at least 2 min before the sample is introduced, to prevent atmospheric contamination.

The external standard calibration technique is generally used by analyzing aqueous composite standards. These standard solutions are treated exactly like the samples and transferred rapidly from their storage vial to the sparger with a syringe, thus minimizing the loss of volatile analytes through volatilization. When analyzing complex aqueous matrices containing a high salt content, the purge obtained with these standards should be compared with that for a real sample by analyzing fortified samples. A surrogate analyte, not present in the matrix, could also be added in the sample to monitor any change in purge efficiency with each sample matrix.

6.3 Analytical Performance

Table 5 gives the analytical performance reported by different groups for THM analysis by the PT technique. The DLs obtained in the 1980s with packed columns were at the 0.1 µg L\textsuperscript{-1} level, which is comparable to those with DAI, LLE or HS. However, the more recent use of ECDs and capillary columns with some sort of analyte refocusing at the head of the column has improved tremendously the sensitivity of the PT technique, with DLs one to two orders of magnitude below the 1 ng L\textsuperscript{-1} level.\textsuperscript{23,38} The precision is very good and is generally <6\% even at the low nanograms per liter level. Finally, the linearity of the technique has been shown by Lépine and Archambault\textsuperscript{38} to extend over four orders of magnitude from 1 to 10\textsuperscript{4} ng L\textsuperscript{-1}, taking full advantage of the large dynamic range of the ECD.

6.4 Advantages and Limitations

The major advantage of the PT technique lies in its superior analytical performance. The sensitivity is unmatched by other techniques and comes from the fact that a relatively large sample can be analyzed and that almost all of the analyte present in the sample is injected into the GC column. The precision is also very good even at concentrations down to the nanograms per liter level.

Like the HS technique, the major disadvantage of PT is the requirement for another piece of equipment to be added to the conventional gas chromatograph. Also, in order to achieve the very low DLs already mentioned, the gas chromatograph should have cryogenic possibilities, either by lowering the whole oven to subambient temperatures or by an add-on unit which could be purchased with the PT unit. Finally, the technique cannot be easily automated, and unattended analysis of a large number of samples can only be achieved through the addition of an external autosampler to the standard PT unit.

One limitation of the technique is that some environmental samples, where surfactants might be present, tend to foam when purged with the inert gas and the frit sparger cannot be used. For such samples, some manufacturers suggest the use of a different sparger made of a glass tube in which the gas is introduced through a stainless-steel needle, giving a stream of large bubbles. However, the purge efficiency is not as good as with the frit sparger.

7 COMPARISON OF THE ANALYTICAL TECHNIQUES

In this article, we have described the four major analytical techniques routinely used for THM analysis in water and a comparison of their major characteristics is given in Table 6. They all have some advantages and drawbacks, which will guide chemical analysts in selecting the technique that best suits their needs, depending on the field of activity and the instrumentation available.

First, we should say that it is one case where the technology largely precedes the regulatory requirements. With high-efficiency capillary columns now commonly available and the high sensitivity of the ECD, all these techniques have DLs at or below 0.1 µg L\textsuperscript{-1} for each of the
four THMs, which is more than adequate for monitoring these analytes in drinking water or beverages. Even in more restrictive applications such as the determination of the background level in natural water samples (lakewater or seawater) or in the nuclear power or semiconductor industry, where high-purity water is needed, this level of detection is sufficient. However, if someone has a special application which requires the very lowest detection achievable, the PT technique is the one to choose. With a purge efficiency close to 100% for these volatile compounds, all the molecules present in a relatively large water sample (typically 5–25 mL) are injected into the GC column, whereas the other approaches have some limitations in that respect. In HS, the amount of analyte introduced into the GC column is limited by the partition coefficient of each analyte between the water and gas phases and the size of the HS aliquot that is injected. However, with cryogenic refocusing at the column head, large loop injection or a long transfer time (depending on the system used) can be used to obtain a DL close to that of the PT technique. In DAI and LLE, the size of the liquid aliquot that the GC column can tolerate (only a few microliters) is the limiting factor.

The complexity of the matrix to be analyzed can also dictate the choice of an analytical technique. With the gas-partition techniques such as HS and PT, since only the volatile compounds are isolated and injected into the GC column, any aqueous matrices can be analyzed. The only exception is the presence of synthetic or natural surfactants, which tend to foam in the PT sparger. In contrast, DAI is limited to relatively clean matrices since everything in the sample is injected onto the column. In LLE, the THMs are isolated from inorganic salts but other organic compounds can be extracted along with the THMs and cause some interference or deteriorate the column performance.

Other more practical aspects, such as the instrumentation required, the simplicity of manipulation, the possible automation and the analysis time, can be considered. If the samples are relatively clean and the sensitivity is not a problem, then DAI is the simplest method. It requires no manipulation of the sample, gives fast results and a large number of samples can be analyzed with an autoinjector on the gas chromatograph. The HS technique also comes close to DAI in terms of simplicity of operation. If the water is introduced into the HS vial at the sampling site, then the only action necessary is to put the vials in the system and start the run. Of course, it requires the purchase of an additional piece of equipment, but the investment can be worthwhile for routine analyses of large numbers of samples, especially when matrix or sensitivity problems may be an issue. The PT method is also easy to perform and needs no manipulation other than taking an aliquot from the sampling vial with a syringe and injecting it into the sparger. However, this operation is performed manually and can only be automated by the addition of a separate autosampler. Finally, LLE is by far the most time-consuming procedure and is not well suited for routine analysis of large numbers of samples. It is, however, a good reference method and may be chosen when the limited number of samples does not justify the purchase of an HS or PT unit, and when DAI is not possible because the gas chromatograph is not equipped with a cool on-column injector or because of matrix problems.

Water samples from underground wells or aquifers contaminated by middle distillate fuels exist in one of two forms. Either the water sample collected from the well shows a layer of floating fuel, or the sample contains the dissolved hydrocarbons from the leaking fuel. In the worst case scenario, that of a floating fuel, the fuel layer is usually collected and analyzed by gas chromatography (GC). The GC profile of the fuel layer is compared to the GC profile of different candidate fuels to determine the fuel type responsible for the contamination of the well.

Pattern recognition (PR) methods offer a better approach to the problem of matching the gas chromatograms of jet fuels because these methods involve less subjectivity in the interpretation of the data. PR methods can identify fingerprint patterns in GC data characteristic of fuel type, even if the fuel samples have been subjected to a variety of conditions. Hence, discriminants can be developed that are relatively insensitive to the changes in the overall GC profile data of the original fuel due to contamination, analytical error, or weathering.

1 INTRODUCTION

Groundwater is the only source of potable water for more than half of the individual households and communities in south-eastern USA. Its possible contamination by fuels stored in leaking underground tanks or pipelines at or near military airfields has prompted the United States Air Force to fund the development of new methods for the identification of fuel materials recovered from subsurface environments. Burgeoning interest in techniques that can establish the type of fuel responsible for the contamination of an underground well or aquifer is motivated in part by the clean-up costs, legal fees, and fines incurred by the polluter.

Water from underground wells or aquifers contaminated by a leaking fuel exists in one of two forms: either the water sample collected from the well has a layer of floating fuel, or the sample contains dissolved hydrocarbons from the leaking fuel. In the worse case scenario, that of a floating fuel, the fuel layer is usually collected and analyzed by GC. The GC profile of the fuel layer is compared to the GC profile of different candidate fuels to determine the type of fuel responsible for the contamination of the well.

Usually, the gas chromatogram of the fuel spill and a number of suspected sources are compared visually, in order to obtain a best match. However, this approach to fuel spill identification is subjective and suffers from the drawback that it does not take into account the influence of weathering on the overall GC profile. Weathering can cause oxidation of aliphatic hydrocarbons, evaporation of lower-molecular-weight alkanes and alkenes, or dissolution of aromatic and other water-soluble compounds in the fuel. (The net result is that differences exist between the gas chromatograms of weathered and unweathered fuels.) Changes in GC operating conditions caused by small variations in the temperature-programming rate of the capillary column can also be a serious problem, complicating the identification of a fuel. Finally, changes in the GC profile due to variations in the resolution of the column over time

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
can also have a deleterious effect. Thus, evidence based on visual analysis of gas chromatograms is not always persuasive in a court of law, especially in cases involving an unweathered fuel identified as the source of a fuel spill, because of differences between gas chromatograms of weathered and unweathered fuels.

The nature of the complex mixture that constitutes a jet fuel suggests that a systematic comparison of gas chromatograms be made, in order to ensure that differences between GC profiles of various fuel types are significant. This is why PR methods\(^{(6-9)}\) are used to match the gas chromatograms of fuel spills to suspected sources instead of direct data-based methods such as visual analysis or library search techniques.\(^{(10)}\) PR methods involve less subjectivity in the interpretation of GC data than visual methods. The application of multivariate data analysis methods (of which PR is one example) to the fuel spill identification problem is also advantageous for other reasons. First, PR methods can identify features (i.e. GC peaks) in the chromatograms that are characteristic of fuel type even though the fuel samples in the data set have been subjected to a variety of conditions. Hence, discriminants can be developed from the data that are relatively insensitive to changes in the overall GC profile of the original fuel due to weathering, contamination, or analytical error. Second, the discriminatory information sought often consists of subtle variations in relative peak intensities distributed across several peaks in the gas chromatograms. PR methods are especially well suited for extracting this type of information from the large amount of qualitative and quantitative data present in the gas chromatograms of processed fuels. Third, PR methods rely heavily on graphics for the presentation of results. For example, the visual presentation of gas chromatograms as points in a principal component map allow the scientist or engineer to uncover hidden relationships within the data, for example to find distinct sample subgroups in a data set. Clearly, the scientist or engineer can play a more interactive role in the data analysis when using PR methods to analyze the data, which will result in a definite advantage, if one is interested in a careful analysis of the data.

2 PATTERN RECOGNITION

2.1 Definition

PR methods were originally developed to solve the class membership problem. In a typical PR study, samples are classified according to a specific property using measurements indirectly related to the property of interest. An empirical relationship or classification rule is developed from a set of samples for which the property of interest and the measurements are known. The classification rule is then used to predict this property in samples not part of the original training set. The set of samples for which the property of interest and measurements are known is called the training set. The set of measurements that describe each sample in the data set is called a pattern. The determination of the property of interest by assigning a sample to its respective category is called recognition – hence the term “pattern recognition” – because recognition is accomplished using the set of measurements that characterize each sample in the data set.

For PR analysis, each fuel sample is represented as a data vector \( x = (x_1, x_2, x_3, \ldots, x_j, \ldots, x_n), \) where component \( x_j \) is a measurement, such as the area of the \( j \)th GC peak. In other words, each fuel sample can be considered as a point in an \( n \)-dimensional measurement space. The dimensionality of the measurement space corresponds to the number of measurements that are available for each sample. A basic assumption is that the distance between pairs of points in this measurement space is inversely related to the degree of similarity between the corresponding samples. Therefore, points representing samples from one class will cluster in a limited region of the measurement space distant from the points corresponding to the other class. PR is a set of methods for investigating data represented in this manner, in order to assess its overall structure, which is defined as the overall relationship of each sample to every other sample in the data set.

2.2 Class Membership Problem in Fuel Spill Identification

The class membership problem in fuel spill identification can be formulated as follows. Given a collection of potential source fuels which are characterized by a set of measurements made on each source sample, is it possible to classify the various fuel samples according to fuel type by using a set of measurements believed to be related to the property of interest? Can the classification rule, developed from a set of samples for which the fuel type and measurements are known, be used to predict the fuel type of spill samples that were not part of the original training set? Can we determine the components of the spill sample most related to fuel type, bearing in mind that the composition of a spill sample may differ significantly from the source due to contamination and or weathering? For PR analysis, each fuel type (i.e. class) is represented by a large number of fuel samples; the measurement variables, which are areas of selected GC peaks, are obtained from the gas chromatograms of the fuel samples.
The PR approach to fuel spill identification assumes that the fuel type is uniquely defined by the fuel’s chemical composition. For example, jet fuels are manufactured only to meet certain specifications (flash point, vapor pressure, freezing point, etc.). Their composition is only loosely governed by military and civilian fuel specifications. Nevertheless, the chemical composition of a fuel dictates its physical properties. (The composition of a complex mixture uniquely defines its properties.) Hence, it is logical to assume that all fuels can be classified by type on the basis of their GC profiles because a gas chromatogram of a fuel contains information about its chemical composition. In the context of fuel spill identification, PR can clearly be defined as an analytical approach that utilizes mathematical, statistical, and other methods of formal logic to determine by indirect means the properties of fuels that otherwise would be very difficult to measure. Indirect observation of these properties (e.g., fuel type) is feasible provided that information about the chemical composition of the fuel is available because the properties of substances such as fuels are uniquely defined by their chemical composition.

The data analysis approach used to identify fuel type – indirect observation of the properties of a substance – actually employs the data to suggest the classification model. This rather unusual approach is possible because GC profile data usually contain a large number of interrelated measurement variables. To understand why GC profile data sets are redundant, consider JP-4, which is a mixture of alkanes, alkenes, and aromatic hydrocarbons. The gas chromatograms of JP-4 fuels (Figure 1) are characterized by a large number of early-eluting peaks that are large in area. There are only a few late-eluting peaks, but their size is small. Clearly, there is a strong negative correlation between the size of the early- and late-eluting peaks of JP-4. Furthermore, many of the alkane and alkene peaks are correlated, which is not surprising as alkenes are not constituents of crude oil but instead are formed from alkanes during the refining process. Finally, the specific property of a fuel most likely to be reflected in a high-resolution gas chromatogram is its distillation curve, which does not require all 85 peaks for characterization. Hence, the 85-peak gas chromatograms of JP-4 fuels do not necessarily require 85 independent axes to define the position of the data points in the pattern space. The data can be described in terms of a few latent variables that are linear combinations of the original measurement variables. Although these latent variables cannot be measured, they can be generated directly from the data using a technique called principal component analysis (PCA).

2.3 Principal Component Analysis

PCA is the most widely used multivariate analysis technique in science and engineering. It is a method for transforming the original measurement variables into new, uncorrelated variables called principal components. Using this procedure is analogous to finding a set of orthogonal axes that represent the directions of greatest variance in the data. (The variance is defined as the degree to which the data points are spread apart or scattered in the n-dimensional measurement space.) Often, only two or three principal components are necessary to explain all of the information present in (p-dimensional, p ≥ 3) compositional data. Hence, PCA can be applied to high-dimensional data to affect dimensionality reduction, in order to identify and display structure, classify samples, or identify outliers.

Dimensionality reduction or data compression is possible using PCA because of correlations between measurement variables. Figure 2 shows a plot of 15 hypothetical JP-4 fuel samples in a two-dimensional measurement space. The coordinate axes of this measurement space are the flash point and freezing point of the JP-4 fuel samples. There appears to be a relationship between the two measurement variables, flash point and freezing point, of the JP-4 fuel samples. This relationship suggests that the flash point and the freezing point are correlated because fixing the value of the flash point limits the range of values possible for the freezing point. If these two measurement variables were uncorrelated, the enclosed rectangle in Figure 2 would be fully populated by JP-4 fuel samples. Because information is defined as the scatter of points in a measurement space, it is evident that correlations between measurement variables decrease the information content of this space. In other words, the data points are restricted to a small region of the measurement space and may even reside in a subspace in the case of strongly correlated measurement variables (Figure 3).
ENVIRONMENT: WATER AND WASTE

Figure 2: Fifteen hypothetical JP-4 fuel samples projected onto a two-dimensional measurement space. Because the freezing point and flash point are correlated, the data points are restricted to a small region of the measurement space. (Adapted from John Mandel, ‘The Regression Analysis of Collinear Data’, *J. Research of the NBS*, 190(6), 465–476 (1985).)

Variables that are highly correlated, i.e. have a great deal of redundancy, are said to be colinear. Colinearity between measurement variables is a strong indication that a new set of basis vectors can be found that will be better at conveying the information content present in data than axes defined by the original measurements. This new basis set is linked to variation in the data. In other words, a new coordinate system based on variance can be developed to display the data – principal components define the variance-based axes of this new coordinate system. The largest principal component is formed by determining the direction of largest variation in the original measurement space and modeling it via a line fitted by linear least-squares which passes through the center of the data. The second largest principal component lies in the direction of next largest variation; it passes through the center of the data and is orthogonal to the largest principal component (Figure 4). The third largest principal component lies in the direction of next largest variation; it passes through the center of the data and is orthogonal to the first and second largest principal components, and so forth. Each principal component captures a different source of variation or information in the data. (Variation is the same as scatter, and scatter equals information.) The maximum number of principal components or variance-based axes that can be extracted from the data is the smaller of either the number of samples or number of measurements in the data set, as this number defines the largest number of independent variables in our data.

PCA takes advantage of the fact that a large amount of data is generated in fuel spill identification studies. The data have a great deal of redundancy and therefore a great deal of colinearity. Because the measurement variables are correlated, 85-peak gas chromatograms do not necessarily require 85 independent orthogonal axes to define the position of a sample point. Using PCA, the original measurement variables, which constitute a correlated axis system, can be converted into an orthogonal system, which removes correlation by forcing the new axes to be independent. This requirement dramatically reduces the dimensionality of the data because only a few independent axes are necessary to

Figure 3: In the case of strongly correlated measurement variables, the data points may reside in a subspace of the original measurement space. (Adapted from Richard G. Brereton, *Multivariate Pattern Recognition in Chemometrics*, illustrated by case studies, p. 108, with kind permission from Elsevier Science, Amsterdam, 1992.)

Figure 4: Principal component axes. The third principal component only describes noise in the data. (Reprinted from S Brown, ‘Chemical Systems Under Indirect Observation: Latent Properties and Chemometrics’, *Applied Spectroscopy*, 49(12), 14A–30A (1995), with kind permission from SAS.)
describe the data. The gas chromatograms of a set of fuel spill samples may lie in a subspace of the original measurement space, and a plot of the two or three largest principal components of the data can help us to visualize the relative position of the gas chromatograms in this subspace. Thus, it is possible to identify important relationships in the data – that is, find similarities and dissimilarities within a set of data, by examining principal component plots of the data.

2.4 Information Content of Principal Components

A measure of the amount of information that is conveyed by each principal component is its variance. For this reason, the principal components are usually arranged in order of decreasing variance. The most informative principal component is the first and the least informative is the last. Hence, one would expect that only the first few principal components should convey information about the effect of interest, if the data is collected with due care, because most of the information or variance in the data should be about the effect that we seek to study. However, the situation is not always so straightforward. Each principal component describes some amount of signal and some amount of noise in the data because of accidental correlation between signal and noise. The larger principal components primarily describe signal, whereas the smaller principal components essentially describe noise. When so-called smaller principal components are deleted, noise is being discarded from the data, but so is a small amount of signal. However, the enhancement obtained in signal-to-noise more than compensates for the biased representation of the signal that results from discarding principal components, which contains a small amount of signal but a large amount of noise. Hence, plotting the data in a coordinate system defined by the two or three largest principal components usually provides more than enough information about the overall structure of the data while simultaneously enhancing signal-to-noise.

2.5 Implementation of Principal Component Analysis

The procedure for implementing PCA is as follows. First, the samples or data vectors are arranged in the form of a table or matrix. Each row of the matrix is a sample, and each column of the matrix is a measurement variable. It is essential that each variable encodes the same information. For example, if measurement 5 is the area of a GC peak for benzene in sample 1, it must also be the area of a GC peak for benzene in sample 2, sample 3, . . . sample N.

The data matrix is usually centered about the mean, that is the mean of a column is subtracted from each element of that column. The effect of mean centering on a data matrix is to adjust the means of the columns to zero. To ensure that each variable has an equal weight (and therefore an equal effect) in the analysis, the data can be autoscaled. In other words, the data are first mean centered and then each element of a column is divided by the standard deviation of that column. Autoscaling adjusts the measurements so that each variable has a mean of zero and a standard deviation of one. Autoscaling removes any inadvertent weighting of the variables that would otherwise occur due to differences in magnitude among the measurement variables.

The principal components can be computed directly from the data by singular value decomposition. This algorithm generates the score and loading matrix of the data, and the eigenvalues of the principal components. The score matrix defines the coordinates of the data points in the principal component space, whereas the loading matrix defines the relationship between the original measurement variables and the new basis vectors describing variation. In other words, the principal components of the data can be reconstructed from the original measurement variables using information contained in the loading matrix. The eigenvalues tell how much variation in the data is contained in each principal component. The principal component representing the direction of largest variance in the data has the largest eigenvalue, the principal component representing the direction of next largest variance in the data has the second-largest eigenvalue, and so forth. The amount of information contained in a principal component relative to the original measurement space, i.e. the fraction of the total cumulative variance explained by the principal component, is equal to the eigenvalue of the principal component divided by the sum of all eigenvalues.

2.6 Soft Independent Modeling of Class Analogy

PCA is central to many of the more popular data analysis methods in PR. For example, a classification method based on PCA called SIMCA (soft independent modeling of class analogy) has been developed by Wold et al. In SIMCA, a PCA is performed on each fuel class in the data set, and a sufficient number of principal components are retained to account for most of the variation within each class. The number of principal components retained for each class model will typically be different. Deciding on the number of principal components that should be retained for each class is crucial. Retention of too few principal components can distort the information content in the model about fuel type, whereas retention of too many principal components results in a lower signal-to-noise due to retention of noise-laden principal components. Using a procedure called cross-validation, it is possible to determine the
model size directly from the training set data. That is, we can use cross-validation to find the number of principal components needed to adequately describe the signal in the data while simultaneously reducing the noise by not including the so-called secondary eigenvectors or noisy principal components in the class model.

The modeled variance, i.e. the variance explained by the class model, describes the signal. The noise in the data is described by the residual variance, that is the variance not accounted for by the principal component model. (The residual variance is explained by the so-called secondary principal components, which have been truncated or omitted.) Samples are classified in SIMCA by comparing the residual variance of a sample to the average residual variance of the samples comprising the class. In other words, an unknown fuel sample is projected onto a principal component map defined by the samples of a particular fuel class, such as JP-4. If a so-called unknown lies close to the JP-4 fuel samples in the principal component map, then it is considered to be a member of the JP-4 fuel class. However, an unknown is not considered to be a member of JP-4 if it is distant from the JP-4 fuel samples in the map.

The comparison of residual variances, i.e. the residual variance of an unknown with the average residual variance of the samples that comprise the class, provides a direct measure of the similarity of a sample to a particular fuel class. It is a measure of the sample’s goodness of fit for a given principal component model. In order to provide a quantitative basis for this comparison, an F-statistic can be used (18) to compare the residual variance of a sample with the mean residual variance of the class. The F-statistic can be used to calculate an upper limit for the residual variance of those samples which belong to the class. The final result is a set of probabilities of class membership for each sample.

The advantages of using SIMCA to classify fuel spill data are threefold. First, an unknown is only assigned to the class for which it has a high probability. If the residual variance of a sample exceeds the upper limit for every fuel class in the training set, the sample would not be assigned to any of the fuel classes in the data set. It is either an outlier or comes from an unknown fuel class, that is, one not represented in the data set. Conventional classification methods (19) will forcibly assign the sample to one of the existing fuel classes in the training set, which would be a mistake. Second, some of the fuel classes in the data set may not be well separated. Hence, a future sample might be assigned to two or more groups by SIMCA, which would make sense, given the similar composition of the fuel samples, which comprise the overlapping fuel classes. Third, SIMCA is sensitive to the quality of the data used to generate the principal component models in the training set. As a result, there are diagnostics to assess the quality of the data. The modeling power (20) describes how well a variable helps the principal components to model variation, and discriminatory power (21) describes how well a variable helps the principal components to classify samples in the data set. Variables with low modeling power and low discriminatory power should be deleted as they only contribute noise to the principal component models in the data set.

The SIMCA method can work with as few as 10 samples from each class, and there is no restriction on the number of measurement variables, which is an important consideration in fuel spill identification problems, because the number of measurement variables often exceeds the number of fuel samples. Most classification techniques would break down in these situations because of problems arising from collinearity and chance classification.22,23

2.7 Pattern Recognition Analysis of Gas Chromatography Profile Data

PR analysis of GC profile data is performed in three distinct steps: peak matching, feature selection, and classification.

2.7.1 Peak Matching

Peak matching or peak identification is crucial in preparing gas chromatograms for PR analysis, because PR methods require each object in a data set to be represented as a data vector. Hence, translation of gas chromatograms into data vectors is the first step in any PR study of GC profile data – this requires the determination of the relative location of individual peaks corresponding to the same compound or compounds in the gas chromatograms that constitute the data set. Peak matching is best accomplished using a GC detector that can provide molecular information about the sample, such as a mass-selective detector. Unfortunately, mass-selective detectors are not as linear or sensitive as flame ionization detectors, which is an important consideration because each gas chromatogram is represented as a data vector or point in an n-dimensional measurement space. (Similarity between fuel spill samples is based on a Euclidean distance metric between pairs of points in the measurement space.) Hence, the linearity and sensitivity of the detector are important issues, which is the reason for the flame ionization detector being so widely used in fuel spill identification studies. However, special peak matching software is usually required to translate the gas chromatograms into data vectors when a flame ionization detector is used.
2.7.2 Feature Selection

Feature selection is also crucial in a PR study. It is important that we identify and delete peaks from the data set that contain information about experimental artifacts or other systematic variations in the data not related to the legitimate chemical differences between the various fuel classes in the data set. For fingerprinting experiments of the type that are being considered, it is inevitable that relationships will exist among sets of conditions used to generate the data and the patterns that result. One must realize this in advance when approaching the task of analyzing such data. Therefore, the problem is to use information contained in the gas chromatograms characteristic of the source profile without being swamped by the large amount of qualitative and quantitative information contained in the gas chromatogram due to experimental conditions. If the basis of classification for samples in the training set is other than desired group differences, unfavorable classification results will be obtained for a prediction set despite a linearly separable training set. The existence of these complicating relationships is an inherent part of fingerprint-type data. Hence, the goal of feature selection is to increase the signal-to-noise ratio of the data by discarding measurements on chemical components that are not characteristic of the source profile of the fuels represented in the data set.

2.7.3 Classification

Classification is usually accomplished by methods such as SIMCA which can effectively handle the attendant problems of colinearity and chance classification that occur with data that has a low object-to-descriptor ratio. Hence, PR is about reasoning, using the available information about the problem to uncover the structure within the data. Mean centering, autoscaling, peak matching, feature selection, and classification are an integral part of this reasoning process. Each plays a role in uncovering the structure of the data.

2.8 Genetic Algorithms for Feature Selection and Pattern Recognition

To use gas chromatograms to discriminate between different fuel types, it is necessary to examine the variability of large numbers of gas chromatograms. PR techniques such as PCA are ideally suited for this task, because they can display variability between a large number of chromatograms and show major clustering trends in large chromatographic data sets. Feature selection, i.e. selecting peaks that are characteristic of the fuel type, is a major goal in all of these studies.

Using a genetic algorithm (GA), it is possible to identify peaks in gas chromatograms that contain information about fuel type. A block diagram of a GA developed for fuel spill identification is shown in Figure 5. The GA selects features that optimize the separation of the fuel classes in a plot of the two largest principal components of the data. (In other words, the features selected by the GA yield principal component plots, which show sample clustering on the basis of fuel type.) Because the two largest principal components capture the bulk of the variance in the data, the peaks chosen by the GA contain information primarily about differences between the fuel classes in the data set. (As variance is synonymous with information, feature selection via this criterion causes information about class differences to emerge as the dominant source of variation in the features selected for PR analysis.) In addition, the algorithm focuses on those classes and/or samples that are difficult to classify as it trains using a form of boosting. Samples that consistently classify correctly are not as heavily weighted in the analysis as samples that are difficult to classify. Over time, the algorithm learns its optimal parameters in a manner similar to a neural network. The PR GA integrates aspects of strong and weak learning to yield a “smart” one-pass procedure for PR. The various components of the PR GA are described below.

2.8.1 Population

Selected features subsets are coded as binary strings called chromosomes. Each chromosome describes a unique set of features. A particular feature is present in a chromosome or binary string only if the corresponding bit in the string is set to 1. The length of each chromosome is equal to the number of features in the data set. The number of chromosomes in the initial population is \( \phi \). (Usually, \( \phi \) is set to 100.) The chromosomes or binary strings comprising the initial population (i.e. the population at generation 0) are generated at random to minimize potential bias.
2.8.2 Fitness Function

With each generation, the GA computes class and sample weights (SW). These weights are an integral part of the fitness function, which is based on scoring the features according to their ability to optimize the separation of the different sample types in a plot of the two largest principal components of the data. The PCA routine serves as an embedded information filter, significantly reducing the size of the search space, because it restricts the search to feature sets whose principal component plots show clustering on the basis of fuel type. (If a plot of the two largest principal components for a set of features yields well-separated classes, one can only conclude that the bulk of the variance encoded by the set of GC peaks is about discrimination.) The fitness function of the GA contains both normalization and scoring components.

Normalization is used to adjust SW and class weights (CW) to preserve the following property: the sum of the CW is equal to 100, and the sum of the SW in a class is always equal to the CW. This facilitates the tracking and scoring of the chromosomes between generations. The normalization functions are given in Equations (1) and (2):

\[
\begin{align*}
\text{CW}(c) &= 100 \frac{\text{CW}(c)}{\sum_{c} \text{CW}(c)} \quad (1) \\
\text{SW}_c(s) &= \text{CW}(c) \frac{\text{SW}_c(s)}{\sum_{s \in c} \text{SW}_c(s)} \quad (2)
\end{align*}
\]

where CW(c) is the weight of class c, and SW(c) is the weight of sample s in class c. Prior to the first generation, the user initializes the CW, with the SW being uniformly distributed in a class.

Scoring is performed on each principal component plot, which is generated for each chromosome after the subset of features coded in the chromosome has been extracted. A principal component plot is scored using the K-nearest neighbors. For a given sample point, Euclidean distances are computed between it and every other point in the principal component plot. These distances are arranged from smallest to largest, and a poll is taken of the point’s K-nearest neighbors. For the most rigorous classification, K equals the number of samples in the class to which the point belongs. The sample hit count (SHC), or the number of like-nearest neighbors is 0 ≤ SHC(s) ≤ Kc. The fitness is computed using Equation (3):

\[
\sum_{c} \sum_{s \in c} \frac{1}{K_c} \text{SHC}(s) \text{SW}(s) \quad (3)
\]

The mean sample hit rate (SHR) for each sample over the entire population of chromosomes or feature subsets is computed via Equation (4), and is used to drive the boosting routine, where φ is the size of the population.

\[
\text{SHR}(s) = \frac{1}{\phi} \sum_{i=1}^{\phi} \frac{\text{SHC}(s)}{K} \quad (4)
\]

To understand scoring, consider a data set with two classes that have been assigned equal weights: class 1 has 10 samples, and class 2 has 20 samples. For uniformly distributed SW, class 1 samples will have a weight of 50 and the SW in each class are uniformly distributed. Suppose a sample in class 1 has, as its nearest neighbors, seven class 1 samples in a principal component plot developed from a particular feature subset. Hence, SHC(c)/Kc = 7/10, and the contribution of this sample to the fitness function for the particular feature subset equals 0.7 × 5 or 3.5. Multiplying SHC/Kc by SW(s) for each sample and summing up the corresponding product for the 30 samples in the data set yields the value of the fitness function for this particular set of features.

2.8.3 Reproduction

Selection, cross-over, and mutation operators are applied to the chromosomes. Fit strings are retained and selected for breeding, a process called selection, which is the first step toward population reorganization. The fit feature subsets are then broken up, swapped, and recombined, creating new feature subsets, which are introduced into the population of potential solutions. This process is called cross-over. In this study, the selection and cross-over operators are implemented by ordering the population of strings, i.e. potential solutions, from best to worst, while simultaneously generating a copy of the same population and randomizing the order of the strings in this copy with respect to their fitness. A fraction of the population is then selected as per the selection pressure which is set at 0.5. The top half of the ordered population is mated with strings from the top half of the random population, guaranteeing that the best 50% are selected for reproduction, while every string in the randomized copy has a uniform chance of being selected. (This is due to the randomized selection criterion imposed on strings from this population.) If a purely biased selection criterion were used to select strings, only a small region of the search space would be explored. Within a few generations, the population would consist of only copies of the best strings in the initial population.

For each pair of strings selected for mating, two new strings are generated using a variation of three-point cross-over (Figure 6). As in the case of simple three-point cross-over, the length of each new string is the same as the dimensionality of the data. Unlike simple
three-point cross-over, our cross-over operator is not compelled to preserve order among the exchanged string fragments, which safeguards the loss of information or features in the population. It will become less likely for the population variability to fall below a critical value due to the additional degree of freedom provided by the reordering. Furthermore, our variation of three-point cross-over may be useful in searching for good string arrangements. For example, if the current population has bad ordering, where features with a high synergism are spaced at great distances, simple cross-over would probably destroy potentially important allele packets. However, there is a chance to obtain good allele ordering by using a cross-over operator with a reordering algorithm embedded in it.

In the last step of reproduction, a mutation operator is applied to the new strings. The mutation probability of the operator is usually set at 0.01, so 1% of the feature subsets are selected at random for mutation. A chromosome marked for mutation has a single random bit flipped, which allows the GA to explore other regions of the parameter space. If the GA finds a better point, the genes from this point can invade the population, with the optimization continuing in a new direction.

The resulting population of strings, both the parents and children, are sorted by fitness, and the top $\phi$ strings are retained for the next generation. Because the selection criterion used for reproduction exhibits bias for the higher-ranking strings, the new population is expected to perform better on average than its predecessor. The aforementioned reproductive operators, however, also assure a significant degree of diversity in the population, because the cross-over points and reordering of exchanged string fragments of each chromosome pair are selected at random.

### 2.8.4 Adjustment of Internal Parameters

The GA is able to concentrate its efforts on classes and samples which are more difficult to classify by boosting their weights (Figure 7). There are two stages in boosting. In the first or learning stage, CW are adjusted relative to each other, in order to achieve an optimal configuration. The class hit rate (CHR), which is the average of the mean SHR for the samples in the class, is computed (Equation 5). Those classes with lower CHR values will be weighted more heavily than classes that score well. The change in the CW, which is computed using a neural network (Equation 6), is monitored throughout the run (where $P$ is the momentum parameter for the neural network and is assigned a value by the user). If the average change in the weights is greater than some tolerance, the GA is said to be learning its optimal CW. Once the tolerance is reached, the CW are fixed and the SW in each class become uniformly distributed according to the CW. This initiates the second stage. The momentum,
which controls the rate at which the sample and CW are changed (Equations 6 and 7), is initially assigned a value of 0.8 while the GA is learning, but \( P \) is adjusted to 0.4 once the CW become fixed. These values have been chosen in part because they facilitate learning by the GA but do not cause a particular sample or class to dominate the calculation, which would result in the other samples or classes not contributing to the fitness function.

\[
\begin{align*}
\text{CHR}_g(c) &= \text{Average} \left( \text{SHR}_g(s); \forall s \right) \quad (5) \\
\text{CW}_{g+1}(c) &= \text{CW}_g(c) + P(1 - \text{CHR}_g(c)) \quad (6) \\
\text{SW}_{g+1}(s) &= \text{SW}_g(s) + P(1 - \text{SHR}_g(s)) \quad (7)
\end{align*}
\]

2.8.5 End Criterion

During each generation, class and SW are updated using the class and SHR from the previous generation. \((g + 1)\) is the current generation, whereas \( g \) is the previous generation.) The aforementioned procedure, which involves evaluation, reproduction, and boosting of the potential solutions, is repeated until a specified number of generations are executed or a feasible solution is found.

2.9 Pattern Recognition Approach to Fuel Spill Identification

Computer-based PR methods can be used to automate the classification of hydrocarbon contaminants from underground wells or aquifers. The approach involves the development of discriminants, which can model the chromatographic information that distinguishes the various fuel types from other suspected hydrocarbon sources. PR methodology attempts to increase the power of automated data interpretation to the point that weathering of fuels is not a limiting factor in the analysis.

The PR approach to fuel spill identification is based on four underlying principles. First, each fuel type has a unique chemical composition. Second, the aforementioned fuel class has a characteristic GC profile distinguishable from other sources of hydrocarbons. Third, information from the gas chromatograms can be encoded in such a way to be resistant to noise and interference. Fourth, the entire approach does not require the identity of the compounds responsible for the fouling involved, thus making the development of discriminants amenable to automated implementation.

2.10 Case Studies

PR methods have been applied to a large number of problems in fuel spill identification. Although the procedures selected for a given problem are highly dependent upon the nature of the classification problem, it is still possible to develop a general set of guidelines for applying PR techniques to real data sets. In this section a framework for solving the class membership problem, in the context of fuel spill identification, is presented by way of two recently published studies. In both of these studies, fuel spill samples were classified into their respective categories on the basis of their GC profiles.

2.10.1 Identification of Underground Fuel Spills

The first study involves the application of GC and PR methods to the problem of classifying weathered and unweathered jet fuels. \((26)\) The training set consisted of 271 fuel samples representing six different types of jet fuels (JP-4, Jet-A, JP-7, JPTS, JP-5, and AVGAS) obtained from Wright Patterson Laboratory, OH, and Mulkiteo Energy Management Laboratory, WA. These two laboratories examine batches of fuels purchased for use by the Department of Defense to verify the authenticity of manufacturer’s claims that purchased fuels meet the designated specifications. The fuel samples used in this study were splits from regular quality control standards collected over a 5-year period. The splits constituted a representative sampling of the fuels.

The fuel samples were stored in sealed containers at \(-20^\circ C\) prior to analysis by GC. The gas chromatograms of the neat jet fuel samples were used as a training set (Table 1). The prediction set consisted of 31 gas chromatograms of weathered jet fuel (Table 2). Of the 31 weathered fuel samples 17 were collected from sampling wells as a neat oil phase found floating on top of the well...

Prior to GC analysis, each fuel sample was diluted with methylene chloride. The diluted fuel samples were injected onto a capillary column using a split injection technique. High-speed GC profiles were obtained with a high efficiency fused silica capillary column 10 m long with an internal diameter of 0.10 mm and coated with 0.34 µm of a bonded and cross-linked 5% phenyl-substituted poly-methylsiloxane stationary phase. The column was temperature programmed from 60 °C to 270 °C at 18 °C per minute using an HP-5890 gas chromatograph equipped with a flame ionization detector, a split/splitless injection port, and an HP-7673A autosampler. Gas chromatograms representative of the six fuel types are shown in Figure 8.

The high-speed gas chromatograms were digitized using an HP-3357 laboratory automation system. The gas chromatograms were also peak matched using a computer program that correctly assigned peaks by first computing the Kovat’s retention index for compounds eluting off the GC column. As the n-alkane peaks are the most prominent features present in the gas chromatograms of these fuels, it was a simple matter to compute Kovat retention indices, that is to place the GC peaks...
on a retention index scale rooted on predominant peaks observed in the gas chromatograms. The peak-matching program then analyzed the GC data in three distinct steps. First, a template of unique GC peaks for the set of 271 gas chromatograms was constructed by examining integration reports, and adding peaks to the template that did not match the retention indices of previously observed peaks. Second, a preliminary data vector was produced for each gas chromatogram by matching it against the template. If the peak was present, its normalized area from the integration report was assigned to the corresponding element of that vector. If the peak was not present, it was assigned a value of zero. Tailing peaks were excluded from the analysis and poorly resolved peaks were coalesced. Third, the number of times a particular feature was found to have a nonzero value was calculated. Those GC peaks below a user-specified number of nonzero occurrences were deleted from the data set, whereas peaks that passed the nonzero frequency criterion were retained. The peak-matching procedure yielded a final cumulative reference index containing 56 features though not all peaks were present in all gas chromatograms. Hence, for PR analysis, each gas chromatogram was initially represented as a 56-dimensional data vector, \( x = (x_1, x_2, x_3, \ldots, x_{56}) \), where \( x_j \) is the area of the \( j \)th peak normalized to constant sum using the total integrated peak area.

As outliers can obscure relationships present in data, outlier analysis was performed on each fuel class in the training set prior to PR analysis using the generalized distance test\(^{(30)}\) at the 0.01 significance level which was implemented via SCOUT\(^{(31)}\) Two JP-4, three Jet-A, two JP-7, four JPTS, two JP-5, and two AVGAS fuel samples were found to be outliers and were removed from the database. The set of data – 256 gas chromatograms of 56 peaks each – were standardized and autoscaled so that each variable (peak) had a mean of zero and a standard deviation of one within the entire set of 256 gas chromatograms.

PCA was used to examine the training set data, in order to obtain information about trends present in the GC data. Figure 9 shows a plot of the scores for the two largest principal components of the 56 GC peaks for the 256 neat jet fuel samples: 1 = JP-4, 2 = Jet-A, 3 = JP-7, 4 = JPTS, 5 = JP-5, and 6 = AVGAS. (Reprinted from B.K. Lavine, A.J. Moores, H.T. Mayfield, A. Faruque, ‘Fuel Spill Identification by Gas Chromatography/Genetic Algorithms/Pattern Recognition Techniques’, Analytical Letters, 31(15), 2805–2820 (1998), by courtesy of Marcel Dekker.)

A GA described in section 2.8 was applied to the 256 gas chromatograms to uncover features characteristic of the source profile of each fuel type. It identified features by sampling key feature subsets, scoring their principal component plots, and tracking those samples or classes that were difficult to classify. The boosting routine of the GA used this information to steer the population quickly to an optimal solution. After 100 generations, the GA identified 20 GC peaks, whose principal component plot showed clustering of the fuel samples according to fuel type (Figure 10). The principal component map of these 20 GC peaks suggests that information is present within the gas chromatograms of the jet fuels characteristic of fuel type. As PCA does not directly utilize class information in developing a map of the data, Figure 10 should be viewed as a conservative estimate of the differences in the hydrocarbon composition of the fuels as reflected by the 20 GC peaks selected by the GA.
Figure 10 A plot of the two largest principal components of the 20 GC peaks selected by the GA. Clustering on the basis of fuel type is evident in this plot: 1 = JP-4, 2 = Jet-A, 3 = JP-7, 4 = JPTS, 5 = JP-5, and 6 = AVGAS. (Reprinted from B.K. Lavine, A.J. Moores, H.T. Mayfield, A. *Outliers were removed from the training set.*

A six-way classification study involving JP-4, Jet-A, JP-7, JPTS, JP-5, and AVGAS fuel samples was also undertaken using SIMCA. Principal component models were developed from the 20 GC peaks for each of the six fuel classes in the training set. The number of principal components retained for each fuel class was determined by cross-validating on the total number of misclassifications. In other words, the number of principal components for each fuel class was adjusted until the optimal classification success rate was achieved for the training set. Results from the six-way classification study involving the 256 neat jet fuel samples are summarized in Table 3. The SIMCA classifier has a high recognition rate, i.e. a low apparent error rate, as well as a low bootstrapped and cross-validated error rate. Evidently, the 20 GC peaks selected by the GA contain information about fuel type.

A prediction set of 31 gas chromatograms (Table 2) was used to test the recognition ability of the 20 GC peaks and the discriminant, which these peaks supported. The gas chromatograms of the weathered fuels in the prediction set were run a few months before the gas chromatograms of the neat jet fuels were run. Of the 31 fuel samples in the prediction set 29 were correctly classified using the principal component models developed from the gas chromatograms of the neat jet fuels. Two JP-5 weathered fuel samples were classified as Jet-A, which is not surprising because of the similarity of Jet-A and JP-5 gas chromatograms. Notwithstanding, the high classification success rates obtained for the weathered fuel samples indicate that information about fuel type is also present in their gas chromatograms.

The results of this study are significant for two reasons. First, the change in composition that occurs after a jet fuel is released into the environment constitutes a major problem in fuel spill identification. These changes can be attributed to evaporation of lower-molecular-weight hydrocarbons, dissolution of water-soluble compounds, and microbial degradation. However, the weathered fuel samples used in this study were recovered from subsurface environments, where evaporation and dissolution are retarded. Hence, the predominant weathering factor is probably microbial action, which does not appear to have a pronounced effect on the GC profiles of the jet fuels. This suggests that the weathering of jet fuels in subsurface environments is greatly retarded in comparison to surface spills, thereby preserving the fuel’s identity for a longer period of time.

Second, poorly resolved peaks were coalesced during the preprocessing step, which diminished both the resolution and information content of the gas chromatograms. Nevertheless, the GA was able to extract enough information from the profiles of the neat jet fuels to correctly classify gas chromatograms of the recovered fuels. This would suggest that simpler and cheaper GC instruments should be used to identify jet fuels. Cheaper and simpler instruments makes economic sense, and chemometric techniques such as GAs ensure that information present in chromatograms from these simpler, less informative instruments is extracted as completely as possible. This is the philosophy behind the approach to fuel spill identification described in this chapter, which we believe is
feasible because of the redundant nature of fuel spill data. To understand why GC data of fuels are redundant, consider again JP-4, which is a mixture of alkanes, alkenes, and aromatic hydrocarbons. The gas chromatograms of JP-4 fuels are characterized by a large number of early-eluting peaks that are large in area. There are only a few late-eluting peaks and their area is small. Clearly, a strong negative correlation exists between the early- and late-eluting peaks of JP-4 fuels. Furthermore, many of the alkane and alkene peaks are correlated, which should not come as a surprise because alkenes are not natural constituents of crude oil, but instead are formed from alkanes during the refining process. Finally, the specific property of a fuel that is most likely to be reflected in a high-resolution gas chromatogram is its distillation curve, which does not require a large number of peaks for full characterization. Clearly, an increase in resolution will increase the redundancy, but not necessarily the information content of the chromatographic data.

2.10.2 Solid-phase Microextraction/Gas Chromatography

Although GC has been used in the laboratory to type fuel spills, the method can also be adapted to the field by taking advantage of a sampling technique called solid-phase microextraction (SPME). This micro-scale analytical extraction technique is designed for use with GC (i.e. SPME/GC). It utilizes a fused silica fiber coated with a polymer (e.g. polydimethylsiloxane) to extract organic compounds from aqueous samples. The fiber is attached to a modified syringe, and the constituents of the fuel are extracted by introducing the syringe into the headspace of the sample and depressing the plunger for a specified period of time. (When the plunger is depressed, the polymer-coated fiber is in contact with the sample.) The extraction efficiency of the SPME sampling method is a function of the partition coefficient of the compounds in the polymer coating. Following extraction, the plunger is retracted, and the SPME device is inserted directly into the injection port of the gas chromatograph. The plunger is then depressed, exposing the polymeric coating to the high temperature of the injector port, ensuring thermal desorption of the absorbed molecules. The absorbed molecules are immediately released into the carrier gas stream, where they are swept onto the column for separation and subsequent identification.

Using an SPME sampling device, it is possible to directly sample a layer of floating fuel in a water sample brought to the surface by a drilling rig. Hence, fuel spill identification can be performed on-site via a portable gas chromatograph equipped with a flame ionization detector and appropriate PR software. To test the suitability of SPME for the proposed application, 180 jet fuel samples representing JP-4, Jet-A, JP-7, JPTS, JP-5, and JP-8 were analyzed by headspace SPME/GC (Table 4). The fuel samples, which were obtained from Wright Patterson Air Force Base or Mulkiteo Energy Management Laboratory, were splits from quality control standards used by these laboratories to verify the authenticity of manufacturer’s claims. These control standards constituted a representative sampling of the fuels. Thirteen fuel samples (seven JP-4, four JP-5, and two Diesel) recovered from the subsurface environment near Air Force and Navy airfields were also analyzed by headspace SPME/GC.

The following experimental protocol was used to obtain a GC profile of the jet fuel’s volatile components. Four milliliters of a neat jet fuel were placed in a 40 mL volatile organic analysis (VOA) bottle. A microstirring bar was also placed in the VOA bottle prior to the introduction of the fuel sample to permit stirring of the sample during the SPME sampling period of 10 min. In a previous study 10 min was found to be sufficient to obtain a representative sampling of the volatile compounds present in a jet fuel. The SPME procedures were performed manually using a commercial SPME holder. A single extraction fiber (100-µm polydimethylsiloxane, SUPELCO) was used to sample the headspace of each fuel sample in the training set. Previous studies in our laboratory have shown that recovered fuels cannot be analyzed by direct SPME sampling because of irreversible fiber damage caused by excessive swelling of the polydimethylsiloxane coating, which is a direct result of the fiber being in intimate contact with the fuel layer.

Gas chromatograms of the fuels were obtained using a high-efficiency fused silica capillary column 10 m in length with an internal diameter of 0.10 mm. The stationary phase was a 0.34-µm bonded and cross-linked 5% phenyl-substituted polydimethylsiloxane phase. The GC column was temperature programmed using an HP-5890 gas chromatograph equipped with a flame ionization detector. The column oven was initially set at 40 °C for 3 min, and the column was then temperature programmed at 10 °C per minute to a final temperature of 250 °C and a final hold time of 0 min. The GC was operated in the split

mode (30:1 split ratio) because of the high solubility of the fuel components in the polymer coating of the SPME.

Gas chromatograms representative of the six fuel types in this study are shown in Figure 11.

The gas chromatograms were peak matched using a FORTRAN program called SETUP,\(^{(27)}\) which analyzed the GC data in four distinct steps. Further details about SETUP can be found in the previous case study on identification of underground fuel spills. SETUP yielded a final cumulative reference file containing 84 features although not all peaks were present in all gas chromatograms. For PR analysis, each headspace chromatogram was initially represented by an 84-dimensional data vector, \(x = (x_1, x_2, x_3, \ldots, x_j, \ldots, x_p)\), where \(x_j\) is the area of the \(j\)th peak normalized using the total integrated peak area for each chromatogram as the normalization factor.

Outliers can adversely influence the performance of PR techniques. Hence, outlier analysis was performed on each fuel class (see Table 4) prior to PR analysis using the

---

generalized distance test, which was implemented via SCOUT. Twenty-four chromatograms were identified as outliers and were removed from the training set. The outliers included three JP-4 chromatograms, seven Jet-A chromatograms, three JP-7 chromatograms, three JPTS chromatograms, four JP-5 chromatograms, and four JP-8 chromatograms. The large number of outliers in the data set was surprising and is probably due to some difficulties associated with using the SPME sampling device. (In a previous study involving the same neat jet fuel samples only about 3% of the samples in the training set were outliers.)

The fuels in the previous study had been diluted with methylene chloride prior to their injection onto the same GC column.)

Figure 12 shows a principal component map of the 84 GC peaks obtained from the 156 gas chromatograms that constituted the training set (Table 5). Each chromatogram is represented as a point in the principal component map. The gas chromatograms of the JP-4 fuel samples are linearly separable from the gas chromatograms of the other jet fuels in the principal component map. However, the gas chromatograms of the Jet-A, JP-7, JPTS, JP-5, and JP-8 gas chromatograms overlap, which is not surprising because these are kerosene-based fuels, similar to Jet-A, the fuel used by civilian airliners. Mayfield and Henley reported that gas chromatograms of kerosene-based fuels are more difficult to classify than gas chromatograms of other types of jet fuels, because of the similarity in their overall hydrocarbon composition.

Clearly, feature selection is crucial for increasing the signal-to-noise ratio of the data because measurements on chemical components that are not characteristic of the source profile of the fuels represented in the data set will be discarded. In this study, we used a GA (see section 2.8) to uncover features characteristic of the source profile of each fuel type. The GA identified features by sampling key feature subsets, and scoring their principal component plots. As it trained, the GA focused on those classes and/or samples that were difficult to classify. The boosting routine used this information to steer the population quickly to

Table 5 Training set
an optimal solution. After 100 generations, the GA identified 22 peaks. The principal component map of the 22 chromatographic peaks shows clustering of the jet fuel samples according to fuel type (Figure 13). As the data points are well separated by fuel type in the principal component map, it follows that a similar separation exists in the 22-dimensional measurement space. This conclusion is reinforced by the results of K-nearest neighbor, which was also used to analyze these 22 chromatographic peaks (Table 6). The K-nearest neighbor classification method categorized the fuel samples in the training set according to their proximity to other samples (of pre-assigned categories) in the 22-dimensional measurement space. It is evident on the basis of K-nearest neighbor and the principal component map that information is contained in the 22 peaks characteristic of fuel-type.

The 22 GC peaks identified by the GA served as a starting point for the SIMCA study. The training set data was divided into six classes according to fuel type: JP-4, Jet-A, JP-7, JPTS, JP-5, and JP-8. PCA was performed on each fuel class in the training set to separate the information and noise sources. Truncation of the noninformative sources of variation led to a principal component model for each fuel class. The model size or complexity for each fuel class was determined by cross-validation. For each fuel class, one principal component was used to model the data.

The gas chromatograms in the training set were then fitted to the principal component models, and the residual (the sum of the square differences between an original gas chromatogram and one reproduced by a principal component model) was computed for every gas chromatogram and model. Each gas chromatogram in the training set was classified on the basis of its goodness of fit via an F-test, which was performed using the residual variance of the sample together with the residual variance of the class. The F-test determined whether a sample was inside or outside its assigned class and outside the other classes in the data. A gas chromatogram was assigned to the fuel class for which it had the lowest variance ratio. If the variance ratio exceeded the critical F-value for the class, then it was not assigned to it. Results from the SIMCA six-way classification study involving the training set samples are summarized in Table 7. The recognition rate for each principal component model was favorable.

To test the predictive ability of these GC peaks and the principal component models associated with them, a prediction set of 20 neat jet fuel gas chromatograms and 13 weathered jet fuel gas chromatograms was employed (Table 8). For the neat jet fuel samples, we employed a different polydimethylsiloxane SPME fiber or varied the sampling time of the fiber over the headspace of the fuel, in order to assess the robustness of the SPME sampling technique. The 13 weathered jet fuel samples were obtained from sampling wells as a neat oily phase found floating on top of water. The sampling wells were located at Tyndall or Key West Naval Air Station in Florida. The approach to fuel spill identification taken here, of classifying the gas chromatograms of weathered jet fuels using discriminants developed from the gas chromatograms of neat jet fuels, was taken because the physical and chemical interactions of jet fuel components with a subsurface environment are not yet fully understood.

Every neat jet fuel sample in the prediction set was correctly classified. This result suggests that our SPME sampling technique is robust because variations in sampling time or fiber type did not adversely influence the classification of the neat jet fuels. The recovered fuels posed a more challenging identification problem. Of the 13 recovered jet fuels, 11 were correctly classified. Nine of the 11 were uniquely classified, which would suggest a strong classification of the data. (The two diesel fuel samples were not assigned to any fuel class in the training set, which was construed as a correct classification because diesel fuels were not included in the training set.) However, two of the four JP-5 fuels were classified as Jet-A, which is not surprising as Jet-A and JP-5 are similar in their chemical composition. In a previous study, we were able to correctly classify all of the weathered fuels using chromatographic data obtained by directly injecting fuels diluted with methylene chloride into the

*e Third skim from a sampling well at Tyndall.

*f Second skim from a sampling well at Tyndall.

The method is relatively rapid, sample preparation is minimal, and the instrumentation and software required for analysis is inexpensive and readily available. The chromatographic reproducibility and the discriminatory power necessary for tracing an underground fuel spill to its source can be achieved using conventional GC without resorting to complex clean-up procedures required by so-called traditional methods. Although spectrochemical techniques such as infrared and fluorescence spectroscopy have also been used to characterize other petroleum distillates, they do not show sufficient discriminatory power for jet fuels because the chemical composition of a jet fuel is primarily middle distillates, i.e. C9 to C18 alkanes and alkenes. (Aromatics are only minor constituents.) In addition, contamination of a spill sample by salt, sand, water, or organic material can be a serious problem when using spectrochemical methods because there is no prior separation step. Hence, infrared and fluorescence spectroscopy generally do not yield spectra that would be characteristic of fuel type for these types of materials.

Evidently, there is a loss in classification power when sampling the headspace of the jet fuels using the SPME technique because only the most volatile components are sampled by the fiber.

**3 CONCLUSIONS**

The combination of GC and PR (GC/PR) is an excellent technique for the identification of underground fuel spills.

1 INTRODUCTION

Groundwater pollution by organic compounds has been reported extensively in the USA and Europe.\textsuperscript{(1)} In the USA, 90,000 cases of groundwater pollution were reported in the period 1989–1990.\textsuperscript{(2)} Groundwater contamination results from leakage of organic fluids from underground storage tanks, accidental spills, inappropriate effluent disposal practices and leaching from landfills. The United States Environmental Protection Agency (US EPA) estimated that in 1992 that 1.6 million underground storage tanks were leaking.\textsuperscript{(3)} The Organization for Economic Co-operation and Development has estimated the world market for environmental equipment and related services will increase from US $200 billion a year in 1990 to US $300 billion by the year 2000.

Petroleum products contain VOCs such as benzene, toluene, ethylbenzene, and xylenes (BTEX) which represent a substantial threat to groundwater quality because of their toxicity and aqueous solubility.\textsuperscript{(4,5)} Other VOCs that are potential groundwater contaminants include chlorinated solvents such as trichloroethene (TCE) and tetrachloroethene (PCE) which have been used as industrial degreasers and dry-cleaning solvents.

These compounds are sparingly soluble in water, but have aqueous solubilities orders of magnitude greater than the maximum drinking water standards. For example, benzene (which is a known human carcinogen) has an aqueous solubility of 1790 mg L\textsuperscript{-1} and a maximum drinking water guideline value of 1 µg L\textsuperscript{-1}.\textsuperscript{(5)} Small spills or leaks of these organic compounds have the potential to contaminate large volumes of groundwater.\textsuperscript{(6)}

There are major difficulties involved in determining organic compound concentrations in groundwater. Access to groundwater samples requires the installation of wells or boreholes. Bores inappropriately constructed or installed using solvent-based glues, for instance can result in groundwater samples that are not representative of the aquifer chemistry. Also, replacing stagnant water...
present within the borehole screen and casing with fresh groundwater from the surrounding aquifer by pumping boreholes (purging) has been shown to be critical to ensure representative groundwater samples.\(^7\)

Another major difficulty is the reliability of sampling procedures and analytical techniques. Conventional sampling techniques frequently use synthetic polymers in the construction of monitoring and sampling equipment, such as submersible and gas-operated pumps,\(^8\) and for example polyethylene tubing in pump discharge lines. Studies by Barcelona et al.,\(^9\) Reynolds et al.,\(^10\) and by Parker and Ranney\(^11,12\) confirmed that VOCs are absorbed into polymeric material, including Teflon. The only materials shown not to absorb VOCs were borosilicate glass and stainless steel. Therefore the use of polymeric tubing as pump discharge lines when sampling for organic compounds is of particular concern. Absorption of organic compounds into polymeric pump discharge lines would result in reduced groundwater concentrations. Desorption from contaminated polymeric pump discharge lines could result in contamination of clean groundwater, and give a false positive result. Exposure of groundwater samples to the atmosphere during sampling, storage, and analysis can also cause significant loss of VOCs by volatilization.\(^13\)

Other potential problems with conventional sampling techniques are the potential for degradation of the more reactive organic compounds during transportation of the groundwater samples to the laboratory for processing. The use of on-site extraction techniques\(^14\) can reduce this problem.

In situ on-site monitoring of organic compounds in groundwater has the potential to overcome a number of difficulties and costs associated with conventional sampling, processing, and analysis. In situ sampling can be more rapid and efficient and, where no groundwater pumping is required during monitoring, little disturbance of groundwater occurs.

A number of in situ monitoring techniques have been developed in recent years. Fiber optic chemical sensors (FOCS)\(^15–18\) have been used to measure organic compounds dissolved in groundwater. These FOCS pass light of an appropriate wavelength to the measurement point by optical fiber. The fiber is terminated with a chemical sensor; interaction of the sensor with the target organic molecule changes fluorescence, absorption, or reflectance of the light. Optical couplers at the surface are able to separate reflected light from the excitation light, and this is analyzed using a spectrometer at the surface. These devices are reported to be able to determine individual organic compounds in complex mixtures. However, individual FOCS are required for each compound of interest, which detracts from the usefulness of these devices for in situ measurement in groundwater, where several organic compounds are often present together. Although these in situ monitoring techniques eliminate a number of sampling problems, the equipment needed for these systems is expensive and not readily transportable.

Another type of in situ monitoring device, termed a diffusion cell or dialysis bag, consists of a semipermeable membrane and relies on the transport and partitioning characteristics of gases and organic compounds across the membrane, into a gas phase or solvent to separate them from the aqueous environment. This system eliminates the need to collect a water sample.

Johnson\(^19\) used hexane-filled cellulose dialysis bags suspended in a pond to monitor polychlorinated biphenyl concentrations. Under near steady state conditions, linear uptake of Aroclor\(^2\) 1248 into hexane within the suspended dialysis bag over 32 days resulted in a 100-fold increase in concentration in the hexane. However, the limitations of this technique included the inability to monitor VOCs and provide quantitative results.

Barber and Briegel\(^20\) used diffusion cells consisting of coiled Teflon tubing installed in backfilled boreholes with nylon access lines to the ground surface to measure methane dissolved in groundwater. Cells were purged with an inert gas that equilibrated with the dissolved methane in the groundwater. Patterson et al.\(^21\) and Davis et al.\(^22\) used a similar system to monitor dissolved oxygen concentrations during remediation of contaminated groundwater and soil.

There are a number of laboratory-based analytical techniques used to analyze VOCs. The most commonly used procedure is purge and trap. This process involves purging the VOCs from the water with an inert gas (hydrogen or helium) and trapping them onto an absorbent material. Purge and trap techniques offer extremely good sensitivity because all the VOCs extracted from generally large sample volumes are transferred to the chromatographic column. However, losses of VOCs from breakthrough of VOCs through Tenax traps have been reported. Bianchi et al.\(^23\) observed approximately 15% loss of benzene due to breakthrough when purging through a 90 × 5 mm tube containing Tenax TA at a flow rate of 100 mL min\(^{-1}\) for 60 min. Barnung and Grahl-Nielsen\(^24\) also observed similar losses when purging through a 100 × 4.8 mm tube containing Tenax gas chromatography (GC) at a flow rate of 40 mL min\(^{-1}\) for 12.5 min.

Microextraction has also been used to extract VOCs from water samples.\(^14\) This technique is similar to conventional solvent extraction except that only small volumes of solvent are used and the evaporative concentration step is omitted. This technique is more cost effective than purge and trap, allowing twice as many samples to be analyzed in the same time; however, this technique is not as sensitive.
Other laboratory-based analytical techniques include membrane inlet mass spectrometry (MIMS). This process involves pumping a water sample past a membrane attached to an inlet system of mass spectrometers, and organic compounds from the water sample preferentially diffuse through the membrane into the mass spectrometer where they are detected. LaPack et al. investigated the effects of membrane thickness, temperature, and membrane inlet geometries on the MIMS process. Harland and Nicholson used MIMS to determine volatile chlorinated hydrocarbons in environmental samples from four field sites. Maden and Hayward concluded that there were several alternatives to the conventional silicone membrane material, depending on the aqueous matrix.

Solid-phase microextraction (SPME) involves inserting a fused silica fiber coated with a polymer into an aqueous sample and the organic compounds in the water diffuse into the polymer until equilibration is achieved between the fiber and water sample. The fiber is then removed from the water and inserted into a gas chromatographic injection port where the organic compounds are thermally desorbed. The coating on the fiber can range in thickness from 7 to 100 µm and includes poly(dimethylsiloxane) (a silicone) and polyacrylate polymers. This technique has been used by Arthur et al. to analyze BTEX compounds in groundwater samples. Improvements to this technique have included: automation of SPME using a modified gas chromatographic autosampler; headspace SPME analysis of volatile and semivolatile compounds from air, water and soil matrices; on-line monitoring using SPME and coupling SPME to high-speed isotropic GC.

Membrane extraction with a sorbent interface (MESI) uses a 4 cm hollow fiber silicone tube (0.305 mm internal diameter, 0.470 mm outside diameter) that was placed in the headspace of a water sample and the inside of the tubing was flushed with hydrogen at a flow rate of 2.0 mL min⁻¹. Organic compounds that diffused through the tubing and into the inner gas space were trapped onto a fused silica fiber coated with 100 µm of silicone. The fused silica fiber was then periodically heated to thermally desorb the organic compounds for GC.

Hollow fiber stripping analysis (HFSA) was used by Zander and Pingert and is a similar technique to MESI. This process was a modification to the more conventional closed loop stripping (CLS). Zander and Pingert used microporous polypropylene hollow fibers to partition organic compounds from a water phase into a gas phase, where the organic compounds were trapped on activated carbon. The organic compounds were then stripped from the activated carbon with a solvent and analyzed by GC.

All of these techniques use GC analysis with either flame ionization detection (FID), electron capture detection (ECD) or mass spectrometry (MS) detection. Other analytical techniques have been developed that use similar extraction processes; however, they use specialized sensors to detect the VOCs. Stetter and Cao passed a carrier gas (typically air) through the inner space of a silicone tube in contact with an aqueous solution of chlorobenzene. The gas flow rate through the tubing ranged from 110 to 516 mL min⁻¹. The chlorobenzene in the gas phase was detected using a chlorinated organic vapor sensor. A similar system was developed by Pawliszyn using a solvent rather than a gas to purge the organic compounds from the polymer tubing. The chemical gradient produced from the solvent extraction was measured using a concentration gradient sensor and the response was related to the aqueous concentration.

Although these techniques provide quantitative data of organic concentrations of collected water samples, they do not overcome the problems associated with groundwater sampling (bore construction problems, volatilization, adsorption).

An automated system using a semipermeable polymer coupled to electrochemical sensors has been developed and patented for the monitoring of VOCs in groundwater. This system was initially designed by the Commonwealth Scientific and Industrial Research Organization (CSIRO) in conjunction with the Cooperative Research Centre for Waste Management and Pollution Control. The system enables semicontinuous in situ monitoring of total VOC concentrations in gaseous and aqueous environments. The system operates by purging the polymer tubing with gas at a low flow rate. In aqueous environments, the gas concentration exiting the VOC probe can then be related to an external aqueous concentration according to Henry’s law.

2 THEORY OF VOLATILE ORGANIC COMPOUND PROBES

When polymers are in contact with VOC-contaminated water, the organic compounds partition between the aqueous and polymer phases. At equilibrium, the ratio between the concentration in the polymer and the concentration in the aqueous phase has been termed the polymer–water partitioning coefficient ($K_{pw}$). Partitioning coefficients of selected VOCs between hollow silicone tubing and water over the microgram to milligram per liter aqueous concentration range have been determined. It was found that VOCs were concentrated within the polymer tubing wall between 75 and 2700 times compared
to the aqueous phase. Over the aqueous concentration range tested, $K_{pw}$ values were independent of concentration. Examples of equilibrium partitioning between the polymer and aqueous phases are shown for benzene, TCE, and toluene in Figure 1.

VOCs are also partitioned strongly into the gas phase within the polymer tube, and at equilibrium the gas concentration within the polymer tube could be related to an external aqueous concentration according to Henry’s law. Due to the high storage of VOCs within the polymer, a similar relationship between the external aqueous phase and the internal gas phase of the polymer was found to still hold when the polymer was purged with a gas stream for a short time at a low flow rate. This gas purging technique has been shown to be a reliable technique over the microgram to milligram per liter aqueous concentration range for the organic compounds tested. However, the gas–water partitioning coefficients ($K_{gw}$) at least doubled as the temperature was increased from 10 to 25°C, indicating a significantly greater partitioning into the gas phase inside the tubing with temperature increases, as may be expected from the Henry’s law relationship.

Although the relationship between gas concentration and aqueous concentration is temperature dependent, the effect of temperature can be estimated using the van’t Hoff equation, and for groundwater monitoring large temperature fluctuations are unlikely. Even so, monitoring the purged gas concentration exiting the
polymer tube and the aqueous temperature provides a technique to monitor the aqueous concentration external to the polymer. Examples of equilibrium partitioning at different temperatures for toluene between the internal gas phase of the polymer and the external aqueous phase are shown in Figure 2.

3 OPERATING PRINCIPLE OF VOLATILE ORGANIC COMPOUND PROBES

The VOC unit consists of a probe and a sensor unit. The probe consists of a length of coiled silicone tubing that is intermittently purged with air at 5 mL min⁻¹. The probe also contains a thermistor to monitor environmental temperature. The probe is immersed either in an aqueous, soil, or gas environment. The probe is connected to the sensor unit via a cable (up to 30 m in length) containing influent and effluent gas access lines and a thermistor wire. The access lines are constructed of semi-rigid nylon and found not to significantly sorb/desorb organic compounds for the length of access lines used. For cable lengths greater than 30 m, stainless steel access lines could be used.

The sensor unit contains a solenoid valve, data logger and a gas hydrocarbon sensor. With the solenoid valve, air either passes through or bypasses the probe before reaching the sensor. The solenoid valve is intermittently operated to purge the probe. The data logger controls the opening of the solenoid valve and stores the thermistor and sensor data. A diagram of a VOC probe and sensor unit is shown in Figure 3. From the data logger readings and an appropriate calibration curve, a value for the VOC concentration external to the probe is calculated.

4 ENVIRONMENTAL APPLICATION

4.1 Calibration and Response Times

Calibration of the VOC probe and sensor unit has been carried out in the laboratory. Comparison of measured benzene concentrations in the aqueous phase external to the probe with sensor response data from the VOC probe and sensor unit is shown in Figure 4. Although the response of the VOC probe and sensor unit was not linear, a calibration curve could be established.

The nonlinear response was attributed to the sensor used in the sensor unit, not the VOC probe. A similar nonlinear response was observed when gas samples were monitored directly (no VOC probe used). Also, when gas chromatography/mass spectrometry (GC/MS) analysis was used, linear responses were observed (see Figure 2).

The sensor used in the sensor unit also gave different responses for different classes of organic compounds. Therefore, a single-component calibration curve may not give quantitative analyses for aqueous samples containing a single noncalibrated compound or multicomponents. However, in situ (re)calibration of the sensor unit for quantitative monitoring can be undertaken by collecting groundwater samples from the same location as the VOC probes.

Based on the calibration curve data, the analytical range of the VOC probe and sensor unit for aqueous

![Figure 3 Diagram of VOC probe and sensor unit.](image)

![Figure 4 Typical benzene calibration curve.](image)
Response times to step changes in aqueous concentrations of VOCs ranged between 1.7 and 5.2 h. (39) The response time \( (t_{0.9}) \) was defined as the time required to achieve 90% of the stable aqueous organic concentration after a step change in the aqueous organic compound concentration. These response times were determined from laboratory experiments where the water bath was relatively well mixed. (39) In groundwater systems, mixing of waters is relatively poor, relying only on groundwater flow and diffusion. Therefore, these estimated response times would be minimum values for groundwater systems, and more typical response times may be significantly greater. However, fluctuations in groundwater concentrations would also be slow, of the order of days to weeks depending on groundwater flow velocities.

## 4.2 Interferences

Due to the semipermeable nature of the polymer in the VOC probe and the relatively high gas–water partitioning of the VOCs, the VOC probe and sensor unit detects a relatively narrow range of compounds, thus reducing matrix contamination. Therefore, samples can be analyzed without further clean-up. The only compound that significantly interferes with the VOC probe and sensor unit would be methane; however, the VOC sensor used is approximately two orders of magnitude more sensitive to the VOCs compared with methane.

Temperature does effect the partitioning of VOCs into the probe; however, for groundwater monitoring, large temperature fluctuations are unlikely. Changes in VOC probe and sensor unit responses due to temperature changes are accounted for by monitoring the external temperature and recalculating the aqueous concentration using the van’t Hoff equation.

## 5 FIELD EVALUATION

To assess the VOC probe and sensor unit under field environmental conditions, VOC probes were installed and used to monitor organic concentrations in groundwater at two field sites in Western Australia. Groundwater samples from these field sites were also collected and analyzed using conventional groundwater sampling and analysis techniques. This enabled a comparison of the two techniques and thus an evaluation of the validity of the new technique. At one site, the VOC probes were operated manually to obtain compositional data of groundwater contamination. At the second site, an automated VOC probe and sensor unit was used to obtain total VOC concentrations.

### 5.1 Site Descriptions

Concentrations of BTEX in groundwater were investigated near a petrol service station in the Perth metropolitan area, Western Australia. At this site a leaking underground storage tank had resulted in contamination of the groundwater with dissolved BTEX compounds. The contaminated groundwater plume was over 420 m long, 0.5–3 m thick and 20–40 m wide. The groundwater at this site was anoxic. A monitoring installation was emplaced approximately 80 m down-gradient from the contamination source. At this location, the depth to groundwater was 3.9 m below ground surface, with a maximum plume thickness of 1.5 m. Groundwater velocity at the site was approximately 150 m year\(^{-1}\). Details of the site hydrogeology and the contaminant plume are given by Davis et al. (40, 41).

The second site at a fuel storage facility in Western Australia was contaminated with dissolved BTEX compounds. The water table was located approximately 3.2 m below ground surface. Further details of the site hydrogeology and soil/groundwater contamination are given by Johnston et al. (42).

### 5.2 Construction and Emplacement of the Monitoring Installation

At the service station site, four prototype VOC probes were bundled together to form a multilevel (multidepth) monitoring installation. The centre of each probe was 25 cm apart vertically, which enabled monitoring over a 1.0 m depth interval. Small (4.7 mm outside diameter, 3.1 mm inside diameter) stainless steel minipiezometers with short (5 cm) slotted aluminum screens were also included with the probes in the multilevel installation and screened at the same depth as the centre of the probes. This was done to allow conventional sampling and analysis of groundwater for comparison with data from the VOC probes.

At the fuel storage facility, prototype VOC probes were used during an in situ air-sparging trial. At the main monitoring location, seven VOC probes were bundled together to form a multilevel (multidepth) monitoring installation. The centre of each VOC probe was spaced 1.0 m apart vertically. Additionally, small-diameter (3.18 mm outside diameter, 2.00 mm inside diameter) nylon minipiezometers with short (20 cm) slotted aluminum screens were included in the multilevel installation and screened at a similar depth to the VOC probes. Again, this was to allow more conventional sampling and analysis of groundwater for comparison with data from the probes.

To emplace the installations at each site, a hole was drilled using 50 mm solid augers. A 40 mm PVC casing was then sludged into position and the multilevel installation
was lowered into the temporary-cased bore. The casing was then withdrawn, letting sand collapse around the multilevel installation.

5.3 Sampling of Volatile Organic Compound Probes and Groundwater

At the service station site the multilevel installation was left for 3 months to allow groundwater chemistry to restabilize before sampling commenced. Groundwater and VOC probes were then sampled in triplicate approximately twice a week for a period of 3 months.

VOC probes were sampled manually by passing high-purity nitrogen gas through each probe via the access line at a rate of 5 mL min⁻¹. Probes were purged for 5 min before sampling. During this time, effluent gas from each probe was discharged to the atmosphere. To sample the organic compounds in the effluent gas purged from the probes, absorbent traps (containing Tenax® TA) were connected to the end of the access line for 4 min, and the organic compounds in the effluent gas were collected on the adsorbent traps. The effluent gas was sampled in triplicate. Traps were then transported back to the laboratory where the organic compounds were desorbed from the traps using a Dani tube desorber and analyzed by GC/MS. Details of the analytical technique are given in Patterson et al.(14)

At the fuel storage facility, the multilevel installations were left for 1 week before the air sparging trial commenced. Groundwater was then conventionally sampled 4–20 times per week during the 4-week air-sparging trial using the technique described above. An automated prototype VOC probe and sensor unit (connected by a 15 m cable) was used to monitor total VOC concentrations for each of the seven probes every 3 h. Probes were purged with air for 15 min prior to recording the sensor response.

Groundwater samples from both sites were collected from the minipiezometers by applying suction using a glass syringe. Stagnant water within the minipiezometers was first purged using the same technique. Groundwater samples were extracted on-site using a microextraction technique and returned to the laboratory for analysis by GC/MS.\(^{(14)}\)

5.4 Comparison of Volatile Organic Compound Probe Data to Conventional Analysis

At the service station site, BTEX concentrations measured in the gas purged from within the VOC probes and groundwater temperature data were used to estimate aqueous concentrations of the BTEX compounds in groundwater external to the probes. Lateral movement of the groundwater plume\(^{(40,41)}\) between the time of installation and monitoring resulted in detection of groundwater contamination at only the top monitoring location (4.0 m below ground surface). Various VOCs were measured in the gas collected from the probe at this location. The main compounds identified in the effluent gas were benzene, toluene, ethylbenzene, \(m\)- and \(p\)-xylene (not chromatographically separated), and \(o\)-xylene. Results from the 3 months of field monitoring are shown in Figure 5. Benzene data from the VOC probe showed good agreement with data obtained using conventional groundwater monitoring (\(r = 0.861\)). For toluene, ethylbenzene, \(m\)- and \(p\)-xylene and \(o\)-xylene, results for the early part of the field experiment (between days 120 and 140) indicated that the VOC probe was predicting groundwater concentrations reasonably well. However, between days 140 and 240 the VOC probe was giving higher groundwater concentrations.

Possible reasons for the observed variations in results may be the temperature/\(K_{gw}\) calibration, delays in response of the VOC probe under poorly mixed groundwater conditions, or the techniques may have been measuring slightly different groundwaters due to slightly different monitoring locations.

As changes in groundwater temperature over the 3 month field trial were relatively minor, with the temperature decreasing from 24.0 to 21.2 °C, possible errors associated with the temperature/\(K_{gw}\) calibration would not explain the differences in the observed results. Also, if temperature effects were the reason for the observed results, then the results for benzene should also show the same trend as the other compounds. However, benzene did not show increasing concentrations with time compared to conventional monitoring.

Another possible reason for variations between the VOC probe data and traditionally measured groundwater data for the less-volatile VOCs may be ‘memory’ effects of the polymer due to a combination of the greater \(K_{gw}\) values for toluene, ethylbenzene, \(m\)- and \(p\)-xylene, and \(o\)-xylene (\(K_{gw}\) values between 210 and 610)\(^{(39)}\) compared to benzene (\(K_{gw} = 75\))\(^{(39)}\) and poorly mixed groundwater conditions. With greater \(K_{gw}\) values there is a greater mass of the particular organic compound stored within the polymer. Under poorly mixed conditions such as in groundwater, the greater mass may result in greater inertia in the system when there is a change in aqueous concentrations. Therefore, VOC probes may tend to underestimate concentrations when groundwater concentrations are increasing, and overestimate concentrations when groundwater concentrations are decreasing. However, this possibility would not explain the observed field data, as the VOC probe data was higher than traditionally measured groundwater data during the period when groundwater concentrations were generally increasing.
Another cause for the discrepancies between the probe and the conventional samples for toluene, xylenes, and ethylbenzene may be incomplete desorption from the adsorbent traps.

A further reason for the observed results is that, although the VOC probes and minipiezometers were in close proximity, they were sampling slightly different groundwater. VOC probes covered a depth interval of 20 cm, whereas the minipiezometers only covered a depth interval of 5 cm. Groundwater concentrations at this location varied significantly with depth. No groundwater contamination was detected in groundwater collected from the minipiezometer at the next depth interval (25 cm deeper). Also, the groundwater contamination plume has been observed to move laterally due to changes in flow direction as a result of seasonal recharge.\(^{[41]}\) At this site the benzene plume is larger than the plumes of the other organic compounds, due to lower
degradation and lower retardation of benzene. This may also explain why variations for benzene were not as significant between the VOC probe results and groundwater samples, as was the case for the other organic compounds.

At the fuel storage facility, during the air-injection phase of the air sparging trial, desaturation of the aquifer caused by air injection resulted in air entry into a number of the small-diameter minipiezometers, and these groundwater samples could not be collected. Therefore only snapshot pictures of VOC concentrations could be determined by conventional sampling of these minipiezometers when sparging was halted. Also, the extent and distribution of VOCs could not be estimated accurately using these minipiezometers when air was being injected, due to possible groundwater movement away from the sparging well during air injection and the corresponding return when air injection ceased.

The VOC probes had the advantage that monitoring could be carried out during the air injection phase of the trial, because they rely on an equilibrium between the probe and the external aqueous or gaseous environment. This provided more continuous data. Also, because the process was automated, a greater frequency of data collection was possible. From this monitoring, small timescale trends could be observed which would be difficult to infer from conventional monitoring data.

Plots of total VOC concentrations estimated from VOC probes and conventional sampling with GC/MS analysis are shown in Figure 6 for selected depths. For the GC/MS data, total VOC concentrations were estimated from the summation of BTEX concentrations. The BTEX compounds were the most dominant compounds detected in the groundwater. Other organic compounds detected, such as trimethylbenzenes and two-ring aromatic compounds, contributed to less than 5% of the total detected mass. The response from the sensor unit was calibrated to the total VOC concentrations at the 10 m below-ground location using the GC/MS data.

In general, groundwater VOC concentrations determined from the VOC probes showed good agreement with data obtained from the conventional technique. Once the air sparging trial commenced, both techniques showed that VOC concentrations decreased rapidly at the shallow depths (to 10 m below ground surface) at the main monitoring location. VOC probe data also showed that at a number of locations VOC concentrations decreased during air injection, but rebounded once air injection ceased. This phenomenon was not observed using conventional monitoring techniques, as sampling could not occur during air injection.

This rebound effect provides good evidence of the lateral movement of contaminated groundwater around the probe locations and indicates this monitoring location is likely to be close to the edge of the sparging-effected zone.

The VOC probes demonstrated conclusively the benefits of in situ on-line monitoring of contaminated groundwater. Processes such as groundwater movement during air sparging and rebound once air injection ceased were dramatically demonstrated using the VOC probes at location DP4, 13 m below ground (see Figure 6). However, based on conventional monitoring during periods when air injection was not occurring, it could be assumed that air sparging had no effect on groundwater at the 13 m below-ground location.
ADVANTAGES AND DISADVANTAGES OF VOLATILE ORGANIC COMPOUND PROBES

The field experiments highlighted a number of advantages of these new sampling techniques. VOC probes provided a robust long-term sampling process under aggressive field conditions. As the system only consists of a semipermeable polymer tube attached to access lines, no maintenance of the system was required.

Also, due to the semipermeable nature of the polymer, high-molecular-weight organic compounds (such as humic acids) and inorganic compounds are excluded from diffusing through the polymer, acting as an in situ sample clean-up step prior to sampling and analysis. As a result, little matrix contamination of the samples occurs so that samples can be analyzed without further clean-up.

Also, because of the simplicity and small size of the probes (20 cm), the system can be used for vertical-profile monitoring of groundwater contamination, especially where the depth to groundwater is greater than 8–9 m, where suction sampling of groundwater from simple minipiezometers fails.

Another advantage of this technique is the increase in sensitivity compared to conventional techniques. For this technique, in situ concentration of the organic compounds occurs within the polymer. Therefore, larger volumes of purged gas could be collected to increase sensitivity.

The disadvantage with the VOC probe and sensor unit is the sensor used to monitor VOC concentrations is not yet compound specific, therefore compositional data can only be obtained by collecting the purged gas from the VOC probe and analyzing the gas using conventional techniques such as GC/MS.

CONCLUSIONS

Recently developed VOC probes were assessed under long-term (between 1 and 3 months) field environmental conditions by comparing data obtained from these probes to data obtained by conventional groundwater sampling and analysis techniques. The in situ VOC probes provided a reliable monitoring technique under aggressive and dynamic field conditions. The probes provided data that were comparable to conventional techniques without the labor-intensive sample collection and processing associated with conventional techniques.

The field investigation also demonstrated the advantages of in situ on-line monitoring. Monitoring could be carried out during the air injection phase of the air-sparging trial, enabling groundwater movement and rebound to be demonstrated. Also, with this automated technique, a greater frequency of sampling was possible, enabling small-timescale trends to be observed accurately. Also, because of the length of the probes (20 cm), they can be used for monitoring of changes in vertical-profiles of groundwater contamination, especially where the depth to groundwater is greater than 8–9 m, and suction sampling of groundwater fails.

ACKNOWLEDGMENTS

The authors wish to thank John Rayner, Terry Power, David Briegel, Jack Smith and Dr Chris Barber from CSIRO Land and Water, and Dr Cynthia Joll from Curtin University for assistance with this work. Thanks also to Dr Mark Imisides for critically reviewing the manuscript. Financial support from the Cooperative Research Centre for Waste Management and Pollution Control and BP Oil is also gratefully acknowledged.

Waste extraction procedures (EPs) were developed to identify wastes which have a potential for groundwater or surface water contamination. Procedures are used for both organic and inorganic substances to comply with specific regulatory requirements, for example, to identify wastes which are subject to regulation as hazardous wastes. In the United States, the toxicity characteristic leaching procedure (TCLP) is the most widely used procedure. Volatile organics are extracted using a zero-headspace extractor, while semivolatile organics and inorganic substances are extracted using a bottle extractor. Because the typical batch EP does not measure a fundamental property of a waste, the result is highly dependent on steps in the protocol, particularly the choice of extraction solution. Although batch extraction tests like the TCLP are the most common procedures, other procedures using multiple pHs and multiple liquid:solid ratios have been developed to overcome the limitations of batch tests.

1 INTRODUCTION

EPs have historically been used for estimating the availability of inorganic and organic species from soil. The growth of environmental regulations created the need for waste EPs which could identify “hazardous” wastes by their potential to contaminate surface water or groundwater. The primary application of waste EPs has been to predict concentrations in leachate if the waste were disposed of in a municipal landfill, but applications have been made to other scenarios. Comparisons among the tests have shown the need for improved procedures and improved modeling of the leaching process.

2 HISTORY

Major environmental laws of the 1970s, principally the US Resource Conservation and Recovery Act (RCRA), created a system to manage hazardous wastes from “cradle to grave.” Central to the US waste management system is a set of criteria for the identification of hazardous wastes. The criteria typically used for hazardous waste identification are ignitability, corrosivity, reactivity, and toxicity. Of these, toxicity is technically the most difficult to define, and the most contentious, since it significantly defines the wastes which are regulated as hazardous wastes. The United States Environmental Protection Agency (USEPA) has depended on a combination of listing hazardous wastes and “characteristics” for hazardous waste identification. Since historically one of the major environmental impacts of mismanaged waste was groundwater contamination, the USEPA has used waste EPs to identify wastes which are regulated because they may pose a threat to groundwater. The initial test, the EP, has been replaced by the TCLP. California has developed a similar extraction test, the waste extraction test (WET), for a similar purpose. These tests were all developed with a scenario of disposal in a municipal landfill, where wastes could be exposed to municipal landfill leachate.
3 ENVIRONMENTAL APPLICATIONS

Extraction tests have been applied to a variety of environmental problems; examples of applications are shown in Table 1. Hazardous waste classification is the most important, since it has a major impact on how wastes will be treated, transported, and disposed of. The major variables which affect the performance of extraction tests are listed in Table 2. Of these, the choice of extraction solution is probably the most important, since inorganic ions may be complexed or chelated by agents in the solution.

3.1 Hazardous Waste Classification

The USEPA criteria for hazardous waste identification include toxicity characteristic criteria using the TCLP. If the TCLP extract of a waste exceeds an applicable toxicity characteristic limit, the waste is classified as hazardous, and is subject to regulation.

California and some (non-US) countries have adopted similar waste classification procedures, based on other extraction test systems. Under RCRA, a state system must generally be at least as stringent as the federal system. As a result, most states, with the exception of California, have adopted the TCLP for waste identification. This article compares the TCLP and WET systems.

3.2 Waste Treatment Standards

The USEPA has also adopted the TCLP for determining compliance with waste-specific treatment standards, primarily for inorganic constituents. These standards set extractable limits for treated wastes prior to disposal in a landfill.\(^4\)

3.3 Site Assessment

EPs have been used as part of the risk assessment process for site mitigation. In this process, an extraction test is used to estimate the concentration of regulated substance which may be extracted from contaminated soil or waste. For example, the synthetic precipitation leaching procedure (SPLP) has been used to estimate how much would be extracted by rainfall if contaminated soil or waste were left in place. This result is compared with either generic risk-based criteria or site-specific criteria based on multipathway risk assessment. Alternatively, site groundwater or site leachate can be used to estimate site-specific extraction. Several states have adopted the SPLP to decide whether contaminated soil can be left in place.

4 TOXICITY CHARACTERISTIC LEACHING PROCEDURE

The TCLP was developed by the USEPA to identify wastes which could contaminate groundwater if the waste were disposed of in a municipal landfill. Accordingly, the extraction solution, an acetate buffer, was originally designed to mimic the effects of municipal solid waste leachate, which typically contains organic acids from the decomposition of garbage and other municipal wastes. Because some alkaline wastes can effectively neutralize the acetate buffer, an acidic acetate buffer, pH 2.9, is used in an attempt to compensate for the effect of alkaline waste. The procedure is presented as Method 1311 in SW-846, Test Methods for Evaluating Solid Waste.\(^4\)

Since the EP is used for regulatory compliance, and the result is highly dependent on the actual procedure, regulatory agencies do not allow deviation from the published procedure, and it is not considered a candidate for performance-based measurement systems. A summary of the procedure is provided in Table 3; USEPA Method 1311 should be used for procedural details.

For regulatory purposes, the TCLP is not used if total analysis indicates that regulatory limits could not be exceeded. With solid samples, for example, the TCLP is normally not required if total results are less than 20 times the corresponding regulatory limit.

4.1 Sample Preparation

For liquid wastes containing less than 0.5% solids, the initial filtrate is defined as the TCLP extract. For solid samples, or liquid/solid mixtures, the steps given in sections 4.2 to 4.4 should be followed.

4.2 Zero-headspace Extraction

If the extract is to be analyzed for volatile organic compounds (VOCs), a zero-headspace extractor is used to minimize the losses of volatile compounds.

4.3 Bottle Extraction

Analytes which do not require the zero-headspace extractor (elements, semivolatile organics, and nonvolatile organics) are extracted with a bottle extractor using a rotating extraction device.

4.4 Analysis of Extracts

If the initial filtrate and the final filtrate are miscible, they are combined and analyzed. If they are not compatible, they are analyzed separately and the results are mathematically combined to give a volume-weighted concentration. The analysis of the liquid TCLP extracts is generally done using the same techniques as for other liquid samples. Oily waste samples may produce TCLP extracts composed partially of oil, and will require digestion or extraction that is appropriate for oil-containing samples.

For regulatory purposes, the final concentrations are compared with the corresponding regulatory limits. For waste classification in general, the variability in results, usually dependent primarily on variability in the waste, is addressed by comparing the upper 90% confidence limit of the mean concentration with the regulatory limit. Because the confidence limit of the mean decreases with increasing sample size, the larger the number of TCLP results, the less ambiguous the classification.

5 SYNTHETIC PRECIPITATION LEACHING PROCEDURE

The SPLP was designed to simulate the extraction of substances from soil or waste by percolating rainfall. For soils from east of the Mississippi River, the SPLP uses a pH 4.2 solution to mimic the effect of “acid rain.” Unlike the TCLP, it does not have a strict regulatory application, and it is primarily used in decisions regarding the remediation of contaminated sites. Typically, the SPLP results are used in a fate and transport model to predict potential impacts on groundwater or surface water, using either screening models or site-specific models.

The SPLP is very similar to the TCLP, with the exception of the extraction solution. Table 4 lists the solutions used for various applications.

6 WASTE EXTRACTION TEST

The WET was designed for the same application as the TCLP, namely, to simulate the extraction of regulated substances by municipal solid waste leachate. The most significant difference between the WET and the TCLP is the extraction solution. The citrate buffer used in the WET is much more aggressive than the acetate solution used in the TCLP for some elements. Citrate is known to chelate some elements with much greater affinity than the acetate complexes. Citrate is naturally occurring, and has been found to be an important chelating agent for toxic elements and transuranic elements.

6.1 Sample Preparation

The WET has similar sample preparation procedures to the TCLP and SPLP; however, for solid samples, the samples are milled to less than 10-mm diameter.

prior to extraction. Elemental metals, unless powdered, finely divided, or friable, are not regulated. Fragments of elemental metal are therefore removed during the sample preparation step.

6.2 Extraction Procedure

The WET EP is similar to the TCLP and SPLP, although more flexibility is allowed in the choice of extraction apparatus. Unlike the TCLP, the WET does not include a zero-headspace extractor, and has no precautions for the loss of VOCs during the filtration and extraction steps.

7 OTHER EXTRACTION PROCEDURES

A great variety of EPs have been developed by government environmental agencies and other standard-setting organizations. Generally, they may be classified as (1) batch EPs, like the TCLP; (2) sequential procedures, in which the extraction solution is replaced with fresh solution at a specified interval; or (3) multiple EPs which are designed to estimate fundamental leaching parameters. Procedures may or may not use agitation. In addition to extraction tests, leaching tests can be done with a continuous supply of extraction solution. Some extraction tests are done with leachate from the landfill in which it is proposed the waste be placed.

7.1 Batch Extractions

Table 5 lists examples of batch extraction tests which have been developed by governments for regulatory compliance. Batch tests have the advantages of reduced cost and time, but suffer from the limitation that the test conditions may not simulate field conditions.

7.2 Sequential Extractions

Sequential extractions involve periodically replacing a portion of the extraction solution or replacing the solids with a fresh portion of waste. The intent is to simulate the longer-term release of constituents or to simulate equilibrium conditions. Because of the time involved in sequential extractions, they have not been used widely for regulatory applications.

LEP, leachate extraction procedure; EE, equilibrium extraction; ASTM, American Society for Testing and Materials; MBLP, multiple batch leaching procedure.
7.3 Multiple Extractions

Some multiple procedures have been designed to estimate fundamental leaching parameters, such as availability, solubility, and diffusion. Availability is the maximum quantity of a constituent that can be released into solution under aggressive conditions, such as those in the WET. Solubility is usually measured over a range to estimate the solubility as a function of pH for a specific waste. Diffusion is important for monolithic wastes, such as wastes which have been stabilized with cement, asphalt, or other material, to estimate the rate of release of a constituent.

8 COMPARISONS AMONG EXTRACTION TESTS

As shown in Table 5, extraction tests can be categorized by extraction solution:

1. deionized, distilled, or other purified water,
2. acetic acid or acetate buffer,
3. citrate,
4. other solutions.

Based on the stability of chemical complex formation, the general expected order of aggressiveness of extraction solutions for most metals is: citrate > acetate > purified water. In practice, this is generally the case; citrate tests (e.g. WET) extract more than acetate-based tests (e.g. TCLP), which in turn extract more than purified-water-based systems. Since most organic analytes are neutrally charged, they are relatively insensitive to the pH of the EP. The extraction of organic analytes is primarily determined by their water solubility, but is also affected by agitation, temperature, and the liquid:solid ratio.

8.1 Municipal Landfill Disposal Scenario

The scenario of waste disposal in a municipal landfill is the basis of the TCLP and the WET. These tests assume exposure to landfill leachate, typically assuming a pH of about 5. The complexing ability of the leachate is modeled by acetate in the TCLP and citrate in the WET.

The actual field conditions at municipal solid-waste facilities can vary considerably. Major factors which affect leaching are as follows.

1. The waste streams: municipal solid-waste facilities may accept some quantities of industrial wastes, as well as biosolids from wastewater treatment. Recycling programs can affect the composition of solid waste which is delivered to the facility.

2. Precipitation: the quantity and composition of leachate is driven by the infiltration of precipitation. Landfills located in semi-arid or arid areas may be “tombs” which generate little, if any, leachate during the dry season.

3. Landfill design: leachate may be recovered and recycled within the landfill or disposed of in a wastewater treatment facility. The design and performance of liners may also affect the quality of leachate.

8.2 Monofill Scenario

Some industrial wastes are disposed of in a dedicated landfill, or monofill. Monofill leachate may vary considerably from municipal solid-waste leachate, particularly in pH and absence of organic acids. Because of the variety of wastes which could be placed in a monofill, it is not feasible to design a generic extraction test for all industrial wastes. The SPLP has been used to simulate extraction with percolating rainfall, but has not been used widely for waste classification.

8.3 Industrial Co-disposal Scenario

Co-disposal of waste with treated or untreated industrial waste can expose wastes to landfill conditions determined by co-disposed waste. For example, lime-treated waste can generate leachate with a pH approaching 13, which can release arsenic and other elements in significant amounts. If a waste has been de-listed as a result of treatment, the waste can go to a landfill which is not designed for hazardous wastes.

9 LIMITATIONS OF EXTRACTION PROCEDURES

The identified limitations of published procedures have been revealed by comparison with field data and by comparison with column lysimeter data. The limitations are both element specific and waste specific.

9.1 Comparisons with Field Data

Because batch extraction tests are typically conducted over 18–48 h and generate one datum point, they are not expected to quantitatively predict the long-term leaching of regulated substances. The typical regulatory application of a test is qualitative, that is, whether a waste is classified as hazardous or not. Some extraction tests have not accurately identified wastes with potential for groundwater contamination. For example, the TCLP has failed to identify wastes which have contaminated groundwater with arsenic.
9.2 Oxoanion-forming Elements

The TCLP and WET were designed using acetate and citrate, respectively, to simulate the complexing of regulated elements by municipal solid-waste leachate. Several elements, e.g. antimony, arsenic, molybdenum, selenium, and vanadium, combine with oxygen under field conditions to create oxoanions. Oxoanions do not complex like cations, and as a result may not be extracted by the batch extraction tests. Of these oxoanions, arsenic may be the most important because of its occurrence in wastes and its risk assessment as a human carcinogen.

9.3 Multiphase Wastes

Multiphase industrial wastes pose a challenge to analytical procedures in general, and extraction tests are no exception. Modeling the extraction of multiphase wastes has not been incorporated into the extraction process. As an example, the TCLP uses an initial filtration to separate the solids from liquids. A sample composed of an aqueous phase and a nonaqueous phase may be separated arbitrarily into an initial filtrate, which may be one- or two-phase, and a “solid” which may in fact contain nonaqueous liquid which did not pass through the filter. One consequence is variability in the final result and incompatible liquids in the final filtrate. The development of extraction tests for multiphase liquids is needed, along with models for dense nonaqueous phase liquids, in order to provide reliable estimates of the movement of contaminants from nonaqueous phases into groundwater.

REFERENCES

The determination of total organic carbon and dissolved organic carbon (TOC and DOC) is one of the most important parameters in water quality and environmental analysis today. TOC is composed of particulate organic carbon, DOC and volatile organic carbon, (POC, DOC and VOC). In most waters, DOC is the dominant component of TOC. POC consists of living and nonliving organic particles and can occasionally become quantitatively important. POC, DOC and VOC are operationally defined by the methods used to separate them. POC and DOC are usually separated from each other by filtration, which can introduce errors due to contamination and filter clogging. Other major errors in TOC and DOC analyses are related to contamination and losses during sampling, storage and manipulation. In particular, removal of inorganic carbon by either acidification with sparging or by acidification with evaporation to dryness results in variable loss of VOC.

Commonly used TOC and DOC methods fall into two approaches: wet oxidation and high-temperature combustion (HTC). In both approaches, organic matter is oxidized to CO₂, which is then usually determined by nondispersive infrared (NDIR) absorbance. Two wet oxidation methods are in common use: wet chemical oxidation (WCO) and ultraviolet oxidation (UVO). In WCO, a strong chemical oxidant, usually persulfate, is added to the aqueous sample and the digestion is usually carried out batchwise in a reactor at an elevated temperature. In contrast, UVO digestion is commonly carried out in a quartz coil surrounding a mercury vapor lamp. Thus, UVO methods can be readily automated using flow-injection systems. Two types of HTC methods are currently in use: dry combustion and direct aqueous injection. In dry combustion methods, the sample is acidified, dried and the residue is combusted at high temperature in a sealed tube, usually in the presence of a catalyst. This method is advantageous for the analysis of large samples. In direct aqueous injection HTC methods, samples are injected into a high-temperature column (600–900 °C), which usually contains a catalyst. In recent years, the latter method has become widely used for the analysis of seawater and other waters because it appears to have a greater oxidation efficiency and precision than most of the other methods, and it can be readily automated. However, automated HTC instruments have problems in the analysis of saline samples, in particular, salt deposits in the sample injection system, memory (or carry-over) effects, and system blank evaluation. Recently, improvements in the HTC injection system and column design have addressed these problems.

1 INTRODUCTION

The determination of TOC and DOC is an important and routine measurement in environmental, industrial and regulatory studies. It is used for estimating chemical oxygen demand (COD) resulting from anthropogenic activities, including dispersal of municipal sewage effluents, industrial wastes, agricultural runoff, and eutrophication of water bodies. TOC and DOC analyses are also used for monitoring organics in process water (i.e. cooling water, condensate and boiler-feed waters in power plants), in high-purity water generating systems, in drinking water, in desalination plants, in contaminated groundwater near waste-disposal sites, in sterilization water used in biotechnology and pharmaceutical processes, in semiconductor reclaim water, in raw and processed effluent water from food, paper and textile plants, and in a variety of regulatory and remediation operations. TOC and DOC are also important components of the global carbon cycle. Accurate measurements of these carbon pools are critical in oceanic and climatic models, as well as in evaluating food-web dynamics. For many of the above applications, real-time or near real-time evaluation of the organic carbon (OC) content of the water is often essential. Owing
to the heterogeneity and structural complexity of natural organic matter, its quantification has mainly relied on the determination of the OC content (DOC or TOC, if unfiltered).

Carbon constitutes about 50% of most organic molecules and it is usually determined by oxidation to CO$_2$ by various techniques. The techniques that have been employed to determine TOC or DOC in fresh and seawaters, include WCO, photo-oxidation, dry combustion, and direct injection-HTC. Although the oxidation of organic matter to CO$_2$ would seem to be straightforward, all current techniques have problems.

For example, there are differences in the oxidation efficiencies (i.e. the ability to oxidize completely OC to CO$_2$) as well as the ease of automation among these different techniques. There is also a lack of certified standards and accepted recalcitrant reference compounds for interlaboratory comparisons and for assessing oxidation efficiencies of the techniques. For most techniques, it is difficult to assess the blank, both instrumental and method. Improper assessment of the blanks, together with blank variability, adversely affect the precision and accuracy of TOC and DOC analyses. Poor reproducibility and poor accuracy can also arise from contamination during sampling, sample manipulations (e.g. transfers, filtration and acidification), incomplete sparging of inorganic carbon and sample storage. In this article, both sampling and instrumental aspects of TOC and DOC analysis are discussed.

2 OPERATIONAL DEFINITIONS AND ARTIFACTS

The commonly used units for TOC and DOC are mg L$^{-1}$, ppm, and µM, where 1 mg L$^{-1}$ is about 1 ppm (w/w), and 83 µM. In this article, the ppm and µM notations are used.

The total carbon content of a sample is the sum of all forms of dissolved inorganic carbon (DIC) and TOC. DIC is composed of the dissolved species within the carbonate system, i.e. carbon dioxide, carbonic acid, bicarbonate ion and carbonate ion. The relative proportion of these species depends on pH and on biological and physical processes. TOC is composed of POC, DOC and VOC matter. In most natural waters, DOC is the dominant component of TOC, usually 50 to >95%. POC consists of living and nonliving particles and can become quantitatively important (e.g. 10% or more of TOC) in surface waters during periods of high biological activity, in lakes and rivers during periods of high land runoff, and in sewerage and industrial effluents.

POC, DOC and VOC are operational definitions since their relative abundance depends on the physical methods used to separate them. POC and DOC are usually separated from each other by filtration. However, filtration can introduce major errors. The pore size range most frequently used is 0.2–1.0 µm. Consequently, varying amounts of submicron detritus, microalgae, bacteria, viruses and colloidal substances pass through the filter and are measured as DOC. For samples containing a high particle load, the effective pore size may dramatically decrease during filtration as the pores become progressively clogged. Clogging results in a change in the size distribution of particles retained and passed by the filter and also in an increase in back pressure with time. Too large an overpressure (or underpressure) during filtration will lead to disruption of particles and fragile organisms with the concomitant leaching of their organic-rich dissolved contents into the filtrate. Other sources of error from filtration include adsorption of DOC onto the filter pad and contamination from the air and the filter itself, if inadequately cleaned. To avoid filtration problems, the filtration step is sometimes omitted and only TOC is analyzed. As POC often represents <5%, and usually <1%, of the TOC in many types of water samples (e.g. seawater, lake water, drinking water, cooling water, high-purity water, etc.), TOC is often equal to DOC within the analytical precision.

Two approaches are commonly used to separate TOC from DIC. In one approach, TOC is calculated as the difference between total carbon and DIC, the latter being determined as CO$_2$ released by the sample by either acidification followed by vigorous bubbling with organic- and CO$_2$-free gas (sparging) or by acidification and gentle heating. This approach for estimating TOC is best suited to freshwater samples where the carbonate concentration is low enough (i.e. similar to the TOC concentration) to ensure good accuracy and precision. However, in the case of seawater and alkaline lake water, DIC is present at about 15–50 times higher concentration than TOC. Thus, for these samples, determination of TOC by difference usually leads to a large analytical error. In the other approach, DIC is removed as above and the remaining TOC in the aqueous sample is determined by oxidation to CO$_2$, i.e. TOC is determined “directly” as opposed to “by difference”. For both approaches, complete removal of DIC is critical to obtain accurate and precise TOC values.

Removal of DIC by either acidification with sparging or, in the case of dry combustion techniques, by acidification with evaporation to dryness (in an oven, desiccator, or freeze-drier), results in loss of VOC. The extent of this loss depends on the intensity of the DIC elimination step, with the least loss (usually <1% of TOC) with quick sparging and the most loss (about 5–15% of TOC) by oven drying. Thus, the VOC fraction is operationally defined by the analytical procedure used to strip or remove it from the sample, as opposed to that fraction
which is volatile under ambient environmental conditions (wind and turbulence). A few commercial TOC systems are designed to trap and analyze the VOC fraction.

Because some (usually unknown) fraction of VOC is lost during the DIC removal step, TOC is also operationally defined, and is equal to DOC plus POC plus residual VOC. However, since the VOC fraction lost is usually minor (<1% of TOC), the error introduced by this loss is also usually minor. For humic-rich waters, an additional problem resulting from the acidification step is precipitation of humic acid, which may result in an underestimation of the DOC content.\(^5\)\(^,\)\(^7\)

3 SAMPLING PRECAUTIONS

Probably the largest source of error in TOC and DOC analyses is related to sampling and sample storage.\(^1\)\(^,\)\(^2\)\(^,\)\(^8\) In addition to the errors discussed in the previous section (i.e. from filtration and DIC removal), contamination during sampling and analysis is a major concern.\(^9\) Contamination can arise from incompletely cleaned samplers and sample bottles or from leaching of organic substances (e.g. plasticizers) from new plastic or PVC (polyvinyl chloride) sampling and storage bottles.\(^4\)\(^,\)\(^10\) In sampling of water bodies, samplers are often used that, by design, are initially open and then are closed at the desired sampling depth. As these samplers are lowered, they pass through the organic-rich surface microlayer and this material can become strongly adsorbed onto the inside walls of the sampler and contaminate the sample. Thus, samplers that are initially closed, then opened at depth are preferred.

After the sample is retrieved, subsequent sample handling steps are also critical, especially for low TOC samples. All transfers should be performed in an organic-free atmosphere or at least upwind from any major airborne contamination sources, in particular the operator and fumes. The latter is especially a problem when sampling from research vessels which are notoriously rich in exhaust and galley fumes. After collecting the uncontaminated sample, it must be stabilized as soon as possible, since biological processes can cause large changes in the DOC concentration even within the first hour of collection.\(^11\) Stabilization is usually performed by quick freezing followed by storage at \(-20^\circ\text{C}\), acidification (pH 2–2.5) followed by refrigeration at \(<4^\circ\text{C}\), or addition of a strong bacteriostatic agent (e.g. H\(_2\)Cl\(_2\)). Of course, any chemical addition made to the samples increases the risk of contamination. Thus, considerable care is required to obtain reliable DOC and POC results. The specific precautions and guidelines needed to overcome sampling and preservation artifacts vary with the sampling protocol used and the type of samples being studied. Detailed studies of some of these precautions can be found in the literature.\(^2\)\(^,\)\(^8\)\(^,\)\(^11\)\(^–\)\(^15\) Some specific recommendations and procedures are given in Table 1.

4 MEASUREMENT OF ORGANIC CARBON

Attempts have been made to use the innate ultraviolet (UV) absorption (250–400 nm) of organic matter to estimate DOC, but this approach appears to be limited to specific geographic areas or water bodies where the organic composition of the sampled water does not change appreciably;\(^16\)\(^,\)\(^17\) that is, the fraction of non-UV absorbing DOC remains approximately constant.\(^18\)\(^,\)\(^19\)

Another approach to measuring the organic content of water involves estimating its oxidizability, i.e. COD and total oxygen demand (TOD). However, these methods are mainly useful for organic-rich wastewaters and freshwaters, and are not suitable for uncontaminated drinking water and most natural waters.\(^20\)

The most commonly used TOC and DOC methods fall into two general approaches: wet oxidation and HTC. In both approaches, the organic matter is oxidized to CO\(_2\) which is then determined by any number of techniques: ion chromatography-conductometry, coulometry, titrimetrically using a pH-sensitive indicator, potentiometrically using a CO\(_2\) electrode, gravimetrically, pyrolysis-GC/MS (gas chromatography/mass spectrometry), inductively coupled plasma atomic emission spectrometry (ICP/AES), by conversion to CH\(_4\) followed by flame ionization detection (FID), and by NDIR absorbance. The last technique is most widely used because it is sensitive and interferences can be readily eliminated. Details of CO\(_2\) detection techniques are not addressed in this article.

4.1 Wet Oxidation Methods

Two wet oxidation methods are in common use: WCO and UVO. In WCO, a strong chemical oxidant is added to the aqueous sample after the DIC had been removed by acidification and sparging. Oxidants used include potassium peroxyde, dichromate in sulfuric acid, silver-catalyzed dichromate (Walkey–Black method), perchlorate, silver-catalyzed persulfate (also called peroxydisulfate), platinum-catalyzed persulfate, and potassium persulfate. Persulfate-based methods are the most commonly used. The oxidative digestion of OC is usually performed batchwise using either a sealed glass ampoule or a reusable reaction chamber. Reaction times and temperatures are usually in the range of 0.1–4 h and 90–160 °C, depending on the nature of the sample and oxidant. The CO\(_2\) formed is measured in several ways (see above), but most frequently by NDIR.
The advantages of WCO are that it is analytically simple and relatively inexpensive. However, WCO has some problems. For example, manual WCO methods are relatively labor-intensive and time-consuming. In addition, WCO has been reported to have a lower oxidation efficiency (usually 5–15% lower) compared to other methods, for example photooxidation and oxidation efficiency (usually 5–15% lower) compared to other methods. The precleaned sample container and cap should be rinsed at least three times with sample before filling.

### Table 1: Recommended sample handling and treatment procedures prior to TOC and DOC analysis

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Sampling</td>
<td>Sampling should avoid contamination, for example, from contaminated air from exhaust stacks, automobile fumes, etc. Always collect and handle samples upwind from possible contamination sources. The precleaned sample container and cap should be rinsed at least three times with sample before filling.</td>
</tr>
<tr>
<td>2. Sample container type</td>
<td>Use precleaned borosilica glass bottles, or Teflon™-coated plastic bottles to collect and store samples. Some types of plastic containers (e.g. high-density polyethylene) may also be used if carefully cleaned.</td>
</tr>
<tr>
<td>3. Cleaning glass sample containers</td>
<td>Muffle glassware for about 8 h at 450 °C. When cool, store in a sealed, clean container. Prior to use, rinse inside with 10% HF using a squirt bottle (and using gloves and goggles). Thoroughly flush out the HF with fresh low-carbon deionized water (i.e. direct from deionized water source). Fill the glassware to rim with fresh low-carbon deionized water and cover with caps or aluminum foil. The glassware can be stored this way at least 2 days. Decant the deionized water just before use.</td>
</tr>
<tr>
<td>4. Cleaning Teflon™-coated plastic sample containers</td>
<td>Wash inside of the Teflon™-coated plastic bottle with acetonitrile. Thoroughly flush out the acetonitrile with the fresh low-carbon deionized water and dry at 40–60 °C in a clean oven. (This is a critical step as any trace of acetonitrile left will contaminate samples and result in an elevated DOC concentration). Fill the washed plastic bottles to rim with fresh low-carbon deionized water and cap them, decanting the deionized water just before use.</td>
</tr>
<tr>
<td>5. Sample storage</td>
<td>Samples in glass bottles should be acidified and stored at 2–4 °C. Samples in plastic bottles should be stored at −20 °C or colder. For the latter, acidification is not necessary during storage, but highly recommended immediately after thawing.</td>
</tr>
<tr>
<td>6. Sample acidification</td>
<td>Use low-carbon or carbon-free 20–40% H₃PO₄ (~85% H₃PO₄ diluted by low-carbon deionized water) to acidify samples to a pH between 2–2.5.</td>
</tr>
<tr>
<td>7. Cleaning autosampler vials</td>
<td>Glass vials are cleaned as in step 3 above. If Teflon™ or Teflon™-backed silicon rubber septa are used, they should be cleaned as in step 4 above. The cleaned septa should be stored in a sealed clean container.</td>
</tr>
<tr>
<td>8. Sample sparging</td>
<td>Sparging is needed to completely remove DIC from the acidified sample. This step is critical for accurate determination of TOC and DOC. The sparging gas should be carbon free, such as “zero” air, ultrahigh purity oxygen or nitrogen etc. The sparging time depends on gas flow rate, bubble size and sample volume. For example, for a 100 mL sample and a gas flow rate of 100–150 mL min⁻¹, the sparging time may be 8–10 min. For an automated HTC analyzer (such as the MQ1001 TOC analyzer, MQ Scientific), sparging is performed with the carrier gas automatically just before the sample is injected into the combustion column.</td>
</tr>
</tbody>
</table>

The disadvantages of WCO are that it is analytically simple and relatively inexpensive. However, WCO has some problems. For example, manual WCO methods are relatively labor-intensive and time-consuming. In addition, WCO has been reported to have a lower oxidation efficiency (usually 5–15% lower) compared to other methods, for example photooxidation and oxidation efficiency (usually 5–15% lower) compared to other methods. The precleaned sample container and cap should be rinsed at least three times with sample before filling. But large reagent additions can cause high and variable blanks due to contamination, which in turn leads to lowered precision and higher detection limits, especially for manual WCO methods. One study indicated that at least some of the apparent discrepancy in oxidation efficiency for WCO methods is probably due to improper assessment of the blanks, especially for earlier studies. Another possible cause of the lower oxidation efficiency of WCO methods is the production of volatile reduced organic compounds during the digestion step. These compounds would be lost to the gas phase and go undetected by most CO₂ detection techniques. Many of the problems associated with WCO are overcome by using UVO methods. Most of these methods rely on flow-injection analysis, as opposed to batch digestion used in WCO. Acidified and sparged samples are injected into an aqueous carrier stream, which is usually buffered and contains an oxidant (e.g. persulfate) and sometimes a catalyst (e.g. titanium dioxide, Hg(II),
or platinum) that greatly enhances the UV oxidation rate and efficiency. The digestion is usually carried out in a quartz coil surrounding a medium-pressure mercury vapor lamp. Since oxidative free radicals are continuously produced by photochemical reactions in the UV-irradiated reaction coil, loss of oxidative efficiency during digestion is not a serious problem, as is possible with WCO. The reaction time is typically 5–30 min at 40–90 °C. The CO₂ produced is stripped from the flow stream, dried and detected (usually by NDIR).

In general, UVO instruments are more complex than WCO set-ups. However, since UVO methods can be readily automated, sample manipulation is greatly reduced, which in turn reduces the potential for contamination and improves the sample throughput and precision relative to manual WCO methods. Automation also facilitates near real-time analysis of TOC and DOC in field and industrial applications. Problems in UVO methods can result from a decrease in UV output due to lamp aging, and from differences in lamp-to-lamp performance. Also, ozone venting of the lamp can be a problem for some experimental set-ups. The oxidation efficiency of most UVO methods (about 95%) appears to be between that of WCO and HTC, with the latter assumed to be 100%. Colloidal material such as complex polysaccharides and algal exudates, particulate matter, and some sulfur- and nitrogen-containing organic compounds have been reported to be incompletely degraded by UVO methods, with the apparent exception of the titanium dioxide-catalyzed UV oxidation method. The latter, although promising, has not been widely tested.

### 4.2 High-temperature Combustion Methods

Two types of HTC method are currently in use: dry combustion and direct aqueous injection. In dry combustion methods, the sample is acidified, dried and the residue is combusted at high temperature in a furnace or in a sealed tube, with or without the presence of a catalyst, such as copper oxide or platinum. The CO₂ formed is purified in a series of traps prior to quantification. The initial drying step is critical and has been performed in several ways: oven drying at 60 °C, vacuum drying at room temperature, and freeze-drying. The dry combustion method has several major disadvantages. In particular, the volatile organic fraction is completely lost. Furthermore, the method is time-consuming and does not lend itself to automation or field use. Contamination is a major problem as the dry salts are strong absorbers of organic vapors. To avoid the latter problem, specially designed freeze-dryers must be used and sample transfer steps must be conducted in a clean environment and by an experienced analyst. The main advantage of this method is that large samples can be analyzed resulting in a large analytical signal. This method is particularly useful for stable-isotope analysis of DOC because large samples are needed to obtain a sufficiently large analytical signal.

The disadvantages of dry combustion methods are largely overcome by using direct aqueous injection HTC methods. Acidified and sparged samples (Table 1) are injected into a high-temperature column (e.g. 600–900 °C), which usually contains catalytic materials such as platinum, cobalt oxide, copper oxide or silver oxide. It is generally believed that a catalyst is needed to ensure complete conversion of reduced carbon, including carbon monoxide, to CO₂. At the time of injection, the aqueous sample is rapidly volatilized creating a momentary pressure pulse in the system which needs to be damped. The combustion products are swept through the column with a carrier gas, usually high-purity oxygen, although other gases can also be used. The CO₂ that is produced in the combustion column is then purified and dried through a series of traps prior to detection, usually by NDIR.

### 4.3 Problems Associated with High-temperature Combustion Methods and Applications to Seawater

DOC is the largest pool of reduced carbon in the sea (about 10¹² g-C), a mass comparable to the total mass of carbon in the atmospheric CO₂ reservoir, or to that stored in terrestrial forests or soil humus matter. Despite the large size of the DOC pool in the oceans, the concentration of DOC is low, about 40 µM (0.5 ppm) in deep waters and 80–90 µM (about 1 ppm) in surface waters. As a result of both this low concentration and the high salt content, the accurate, precise and artifact-free determination of DOC and TOC in seawater has been a major problem despite over 30 years of effort. The necessity for accurate and precise determination of DOC in natural waters has increased sharply over the last few years because several large-scale models and major field studies of marine systems have focused on carbon cycling and its relation to global fluxes, climatic fluctuations and food-web dynamics. This need has been partly met through recent concerted efforts, which involved several workshops and community-wide interlaboratory comparisons. Direct injection high-temperature catalytic oxidation has become widely used for the analysis of TOC and DOC in seawater and other natural waters because this method appears to have greater oxidation efficiency, accuracy and precision than most of the other methods. A large number of experimental HTC systems have been built and several commercial instruments are available. However, many of these instruments have problems, particularly in the analysis of seawater. These problems are mainly related to salt deposits in the sample injection
system, memory (or carry-over) effects, system blank evaluation, and motion and vibration sensitivity of NDIR detectors.

The autosampler and injector components of most commercial systems are generally not designed to work with samples with high salt concentrations (e.g. seawater and brines). Many of these injection systems use a sliding metallic or Teflon™ valve, which is susceptible to salt abrasion. In addition to this problem, the high salt content of seawater and brines can cause mechanical and clogging problems in other components of some fully automated TOC instruments. As a consequence, the autoinjection features have sometimes been bypassed or avoided in favor of more reliable manual syringe injection techniques, which are more labor-intensive. Most shipboard TOC analyses are currently being performed by manual injection, often requiring two or three operators working in shifts.

Manual injection systems also have some problems. Most manual systems employ a septumless injection port. The use of this semi-open injector can result in a major disturbance in the gas flow and an increased potential for contamination (e.g. from a contaminated needle). Using a septum-type injector does not solve these problems, as the septum itself can introduce contamination. Another potential problem with manual injection arises from variations in the injection delay interval (i.e. the time between injections), which results in blank variability and consequently in poor precision and accuracy. Thus, for manual injection systems, obtaining high precision for very-low-carbon samples depends on the skill level of the operator. The reason for the injection delay effect is not known. However, this problem can be minimized with the use of an autosampler and autoinjector that employs a short and reproducible injection delay time. In addition, most TOC and DOC analyzers use an autosparging system with a constant sample sparging time to ensure complete DIC removal, which is critical. The use of a constant sparging time also ensures that any minor organic contamination that might be present in the sparging gas would be incorporated reproducibly within the blank.

Memory effects may arise because most HTC column designs have a “cold” zone at the top, where vaporized OC together with sea salts can deposit on the wall in the dead volume above the column packing. During subsequent injections, these deposits may wash off or “flake off” randomly and become oxidized, giving rise to an unusually large peak. Owing to the random nature of this memory effect, it is difficult or impossible to correct for it since it may affect standards and samples differently. Discarding unexpectedly small or large peaks will improve the precision, but this may have a negative impact on the accuracy, especially if the large peaks are due to residual OC deposits from prior samples. Thus, the overall impact may be lowered recoveries and less than 100% oxidation efficiencies for even thermally labile standards.

Problems arising from sample injection and memory effects have been recently addressed through major improvements in the HTC injection system and column design. The improvements include coupling a self-rinsing, loop autoinjector directly to the HTC column via a platinum tube so that the injection process is closed to the atmosphere, thereby increasing the precision and eliminating potential contamination during manual injection. In order to address memory effects, the cold zone at the top of the column was essentially eliminated, which allowed the sample injection to take place entirely within the column’s “hot” zone. This modification eliminated effects due to deposits “flaking off” from the walls. In addition to this modification, a small amount of deionized water was automatically injected immediately after each sample injection to keep salt deposits from building up in the connecting tubing. The deionized water injection also helped to reduce memory effects from sample-to-sample carry-over and to increase the lifetime of the autoinjection valve by washing out residual salts.

The accuracy of TOC and DOC analyses is strongly dependent on evaluation of the system blank, which in turn is dependent on conditioning of the instrument, especially the HTC column. Column conditioning is often accomplished with repeated injections of low-carbon distilled water. Hundreds of injections have been reported to be required to obtain a low and stable blank for Pt-based HTC columns, which is problematic using manual injection. Once the HTC column is conditioned, accurate assessment of the instrument blank depends on the purity of the injected “zero” carbon water. Of the various methods that have been used for producing “zero” carbon water, closed loop injection of the condensed water that is trapped after the HTC column appears to be the most effective.

Most HTC columns are packed with alumina beads containing Pt, supposedly to catalyze the complete oxidation of OC to carbon dioxide. However, these columns are relatively expensive and the catalytic sites may be subject to poisoning or deactivation by salt deposition. It is not clear what function, if any, the catalyst plays in the oxidation process. In fact, several recent studies have shown that complete oxidation can be achieved with HTC columns without a catalyst, for example using pure quartz beads. The latter is less expensive and has a lower blank.

From the above, it is apparent that the precision and accuracy of HTC methods are affected by various factors including the presence or absence of a cold zone (and dead volume) at the head of the column,

Memory and carry-over effects, contamination and salt deposition during injection, variable injection delay time, and sample sparging time. (20,33,34) In addition, variations in carrier gas flow rate and column temperature can have a strong impact on the precision. (34) Most of these sources of error are eliminated or minimized by using a closed self-rinsing autoinjection and autosparging system directly coupled to a noncold zone, low dead volume combustion column. (34) These recent improvements in HTC instrument design should benefit other fields besides oceanography, especially where high precision, low detection limits, salts, or field portability are important. A summary of the advantages and disadvantages of the major TOC and DOC methods is given in Table 2.

WATER ANALYSIS: ORGANIC CARBON DETERMINATIONS

X-ray Fluorescence Spectroscopic Analysis of Liquid Environmental Samples

Philip A. Russell
Oxford Instruments, Oxford, UK

1 INTRODUCTION

X-ray fluorescence (XRF) spectrometry is an instrumental technique used for multielement analysis. It is one of only three techniques available to the modern analyst, the others being mass spectrometry and optical emission spectroscopy, the latter usually being the inductively coupled plasma (ICP) variant. The determination of environmentally sensitive elements in the range P–U in aqueous and/or organic matrices provides challenges to all multielement techniques. With recent improvements in instrumentation and methods design (simplified sample preparation compared with other techniques), XRF, in particular for highly contaminated liquid waste, is becoming the preferred technique. XRF is shown to give the most cost effective and best overall speed of analysis across a range of diverse matrix types. Potable drinking water to highly toxic industrial sludge/waste can be analyzed for either precise ultralow level (parts per billion) or screening purposes, respectively. Energy-dispersive X-ray fluorescence (EDXRF) has provided the best all-round performance with the introduction of dedicated instruments and standard methods for the analysis of environmentally sensitive elements in all forms of liquid matrices.

from the cascading of electrons from outer shells to fill vacancies in inner shells.

XRF spectrometry encompasses many different forms but is based upon two principal techniques:

- wavelength-dispersive X-ray fluorescence (WDXRF);
- energy-dispersive X-ray fluorescence (EDXRF).

The differences between these techniques can be summarized in the following way. WDXRF uses X-ray excitation over a wide energy range in the form of high-voltage (20–100 kV) and -power (200–4000 W) X-ray tube sources with high-resolution detection using X-ray diffraction crystals to separate the elements. EDXRF uses narrow energy range X-ray excitation in the form of X-ray sources to low-voltage/power X-ray tubes; energy-restricting filters and/or secondary excitation targets with broad energy range detection using proportional counters or semiconductor Si(Li) or germanium detectors. The two techniques can often be viewed as complementary. Newer derivations of EDXRF are total-reflection X-ray fluorescence (TXRF) and synchrotron radiation X-ray fluorescence (SRXRF).

XRF spectrometry is used for the qualitative and quantitative elemental determinations of solids and liquids. The element range can be from atomic number (Z) > 11 (Na) for liquid matrices. More typically, Z = 15 (phosphorus) and above is a practical limitation for the quantitative measurement of environmentally important elements in liquid media owing to the affects of sample support films used.

XRF’s true power is not so much in the dedicated analysis of a particular matrix, but its ability to provide a technique for the analysis of a very wide and diverse range of liquid sample types, i.e. methods for ultratrace analysis in waters through to industrial liquid hazardous waste (LHW). The advantages of XRF lie in the technique’s ability to measure simultaneously a wide range of elements often presented in their “as-received” liquid form. Where required, preconcentration techniques for elements in liquid are usually simple.

Detection limits for both “as-received” liquid samples are usually in the 1–10 mg kg⁻¹ range and as much as six orders of magnitude lower for samples prepared by preconcentration, the latter depending upon the instrument type employed. Accuracy and precision vary according to matrix constraints, elements determined and methods of sample preparation used. Accuracy of ±0.3% relative and precision of <0.2% routinely can be achieved for the analysis of clean “as-received” environmental samples. However, as sampling, homogeneity and sample preparation are usually the controlling factors in the analysis of environmental samples, more typical accuracies of ±1% relative and precision levels of 2% can be expected.

Matrix and interelement interference can be problematic when measuring samples of highly variable forms in environmental samples. Speciation analysis can only be carried out through indirect methods of analysis.

Handbooks by Van Grieken and Markowicz¹ and Lachance and Claisse² provide an overview of XRF theoretical principles and techniques. These will be of particular interest to those wishing to obtain a wider appreciation of XRF capability.

Burkhalter³ outlined the long established use of XRF in the analysis of water for metal contaminants using preconcentration techniques. XRF is a well-established technique for geochemical analysis, is used extensively for soil analysis and, as a more recent adjunct, for sludge and wastewater. Reviews by Bacon et al.⁴,⁵ and Ellis et al.⁶,⁷ provide excellent recent summaries of all aspects of XRF instrumentation and applications.

### 2 HISTORY

The analysis of environmental samples using XRF has a relatively short history. The first analyses were based upon WDXRF. Relatively simple matrices such as metals present on filter papers were seen as ideal samples to be measured. The use of preconcentration methods using coprecipitation and newly developed ion-exchange papers in the late 1960s and early 1970s encouraged many workers to develop dedicated methods. Ellis et al.⁸ provide a review of these methods.

The introduction and development of commercial EDXRF instruments in the early 1970s provided a cost-effective qualitative and quantitative measurement capability. The early EDXRF instruments were not capable of measuring complex, highly variable matrices and thus were somewhat restricted in their capability. However, their potential to determine metals and particularly heavy elements was clear. Powerful multielement sequential WDXRF instruments were seen as the only viable quantitative XRF technique owing to its ability to resolve complex overlapping X-ray lines; however, it remained expensive, and not the ideal tool for the analysis of environmental liquid samples.

The introduction of inductively coupled plasma atomic emission spectroscopy (ICPAES) in the early 1980s provided an ideal technique for the analysis of complex samples for all environmentally toxic metals even though the techniques were expensive and time-consuming. Many methods for analysis of solid waste, water and wastewater samples using ICPAES and the earlier developed atomic absorption spectroscopy (AAS) technique...
were developed in the 1980s and integrated into standard analytical protocols such as United States Environmental Protection Agency (USEPA) SW846. These protocols are based upon digestion techniques, becoming more refined with the introduction of microwave digestion. The introduction of such protocols reduced the need for further development in the uses of XRF and not until the late 1980s and early 1990s were instruments developed to compete with the ICP-dominated market.

The increasing use of modern personal computers in XRF instruments and improvements, especially in EDXRF instrumentation, in the mid-1980s gave researchers the opportunity to develop new methods for the analysis not only of waters and wastewater but also LHW samples. The development of TXRF in the late 1980s provided an analytical tool capable of achieving detection limits for metals in water equal to modern inductively coupled plasma mass spectrometry (ICPMS) instruments.

In the early 1990s, EDXRF instruments were developed to provide analytical methods that were capable of determining environmentally sensitive elements such as Hg, As and Cd at regulatory levels in hazardous waste (liquid and solid) without the need for expensive, time-consuming sample preparation.

Currently, EDXRF is providing the main analytical tool for the analysis of hazardous waste in many laboratories. The promulgation of performance-based measurement techniques and methods by organizations such as the USEPA and the American Society for Testing and Materials (ASTM) has allowed XRF, in general, to be accepted as a viable cost-effective alternative to traditional ICPAES and AAS methods used in many laboratories for the analysis of liquid waste samples.

The analysis of a few elements, e.g. Be and B, must be carried out by atomic absorption/emission techniques owing to the limitations of XRF; however, this is compensated by the ability XRF spectrometry to perform the analysis of halogens (excluding F) and S.

Competition in the late 1990s between XRF and ICP as the only multielement techniques available will provide, over the coming years, methods that are based upon the performance needs of both industry and regulators in terms of cost, accuracy and appropriateness.

3 SAMPLE PREPARATION

As with all analytical instrumental techniques, sample preparation plays a crucial role in obtaining data and results that can be viewed as significant. A series of papers by Tatro describing the current sample preparation methods employed by the USEPA for hot-plate and microwave digestion provides an excellent background to the current state of the art in most modern laboratories using AAS and ICP instruments. Wheeler and Van Grieken and Markowicz provide reviews of many X-ray sample preparation techniques, especially those specific to trace metal analysis in liquids. Sample preparation techniques used by XRF can be separated into two main categories.

- Digestion and wet chemical techniques. These techniques share a common history with optical absorption and emission spectroscopic techniques such as AAS and ICP.
- XRF-specific sample preparation techniques. These techniques are based upon minimizing sample preparation.

Environmental analysis of samples requires the understanding of the limitations and sources of error intrinsic within any sample preparation regime. When comparing techniques used for the analysis of “environmentally sensitive” elements, e.g. As, Cd and Hg, especially at trace and ultratrace levels, the sources of error must be related to the quality of information required. Regulatory requirements are based on total element content, and techniques that do not supply this information directly need to be evaluated before data can be reported. Elements such as cadmium, mercury, lead, thallium and other toxic volatile metals are easily lost from samples that undergo extensive chemical preparation and heating.

When comparing methods based on detection limits only, it is easy to eliminate techniques that can provide valuable and accurate data but not the ultimate in detection or element coverage.

XRF benefits from the potential ability to analyze samples in their “as-received” form. The most common method of sample preparation used for the determination of elements at trace level, i.e. 1–1000 mg kg⁻¹, involves placing “as-received” solution in a measuring cup. A thin (1.5–6 µm) polymer film supports the liquid sample. Solutions that are in a pure aqueous or organic form can be determined directly. Samples containing particles and/or multiphase solutions must be pretreated to produce a homogeneous sample prior to presentation to an instrument.

For solid samples such as dried sludge or filter-cake residue taken from liquefied material, the method of pelletizing can be employed. This method can involve grinding or milling of a sample to produce a homogeneous fine powder. The resultant powder is then pressed into a pellet to produce a self-supporting disk that can be placed into the instrument for analysis. In applications where samples are sufficiently fine they can be pressed with no other preparation. Other techniques have been
developed to homogenize samples such as sludges and slurries to produce a methodology that will allow samples to be presented to an instrument in a uniform and repeatable way.

The analysis of environmentally sensitive elements in waters and sludges creates some challenges for the XRF technique. It is often the case that the most environmentally toxic elements require detection limits at levels typically below those that can be achieved by “as-received” sample preparation techniques. For this reason methods of preconcentration are required.

Details of the above sample preparation techniques will be discussed in the following sections starting with filtration and the analysis of the resultant essentially solid sample, then moving on to preconcentration techniques involving element extraction.

3.1 Sample Preparation Using Filtration and Centrifugation

Knowledge of the differing sensitivity of elements across the XRF spectrum, i.e. from low- to high-Z elements, dictates the amount of filtrate needed to achieve a usable detection limit for the elements of interest. A filtrate can be collected for use in two ways. The first is to collect a large quantity that can be subsequently dried and treated as a bulk sample. The second is to minimize the amount collected and to treat the sample as a thin-film coating on the surface of the filter used.

For bulk samples such as filtered sludges where the solid component is large enough, samples can be either transferred to sample cups where a thin polymer film supports the loose material or, if the sample is capable of compaction, pressed into a solid pellet. In the latter case many samples containing large amounts of organic matter are difficult to compress into pellets, hence loose material in a cup is the only option.

Suggested schemes for the analyses of sludge using XRF would be as follows:

- Centrifugation of the sample to separate solids from the liquid phase. The two phases can then be measured separately.
- Solids can be compacted into a pellet or simply placed in a sample cup. Compaction of the solid sample is difficult if the sample is still damp. Accurate measurement of the solid phase assumes that the particle size of the solid is relatively small, i.e. <200 µm. It is often necessary to homogenize the sample prior to pelletizing. This is carried out using a laboratory blender.

The analysis of sludge as pellets or as loosely compacted sample (contained in a sample cup) uses methods similar to those used for solids and soils analyses. The performance of analyses when measuring pressed pellets is better than that of loose powders owing to consistency of sample preparation and their increased density.

Where the particulate content is low, typically 47 mm diameter ashless filter papers are used for laboratory-based analysis. Depending upon the requirements of the analysis, usually a paper capable of achieving particulate entrainment of >0.45 µm is acceptable and may be mandated by methods, especially those used in the water industry.

The filtrates will adhere to one surface of the filter paper, producing a filter cake on the surface. The thickness or total mass of the filter cake is important. If the mass of the filter cake is too high then interelement effects will begin to dominate. It is important to understand that light elements will be affected more by the mass of the filtrate than heavier elements. Therefore, any analysis regime must first establish what elements are required. The lightest element required dictates what the masses should be as these have the lowest sensitivity. Typically 20 mg is a good maximum to achieve. For potable drinking and natural waters this level is reasonable and for preconcentration from 1 L should rarely be exceeded. Actual methods of measuring such filter papers may vary from one instrument to another. These will be discussed further in section 9.

3.2 Sample Presentation to the Instrument

Figure 1(a–c) show typical set-ups of sample presentation used for the determination of analytes in water and wastewater applications. This shows the main types of holders used to retain environmental samples for presentation to spectrometers. All XRF instrument
manufacturers provide appropriate holders for samples, in addition to holders being available from laboratory suppliers of XRF consumables.

3.3 Ion-exchange Papers

Methods are based upon filters impregnated with copolymers using sulfonic acid active sites for cation exchange and quaternary ammonium active sites (chloride ion form) for anion exchange. A disadvantage in their broad use is that their efficiency is controlled by pH; however, this can be used to advantage in obtaining oxidation state speciation information, which is valuable for the interpretation of element toxicity. For a number of very important analytes, e.g. chromium, arsenic, antimony and selenium, the use of pH can be used to separate the more toxic oxidation states.

Ellis et al.\textsuperscript{(8)} used commercially available cation-exchange papers in the form of sulfonic acid copolymers and Varshal et al.\textsuperscript{(12)} used cellulose papers impregnated with aminocarboxylic acid to form the cation-exchange paper. Examination of the use of ion-exchange paper regimes typically shows that the quantitative extraction of elements using strong acid cation-exchange papers is limited by pH. Ellis et al.\textsuperscript{(8)} showed the extraction of Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Ag, Cd, Sb, Hg, Tl and Pb, but the species existing as anions [i.e. As(III), Se(IV) and Sb(III)] were not extracted.

The majority of analytes required to be determined fall into the cation group of elements. Anion-exchange papers are used for more specific separations where information on speciation is sought.

A typical procedure for the use of cation exchange papers would be as follows:

- Adjust the sample pH to the appropriate level, typically 3–5, and add any required buffer.
- Prefilter the sample (100 mL–1 L) through a 0.4–0.5-µm ashless filter to remove suspended particulates.
- Filter the sample through the cation-exchange paper. This can be either multiple passes or through a cascade of papers depending upon the expected concentration levels of elements to be captured and the loading capacity of the filters. Flow rates are usually of the order of 30–50 mL min\(^{-1}\) for a 25–47-mm diameter paper.

Ion-exchange resins are used, but their use in “direct analysis” of the resin is limited owing to the dilution factor of the resin itself and the effect of S or Cl functional groups in attenuating the fluorescence signal, especially from lighter elements. Typically they are used to remove an interfering matrix, e.g. seawater, from the elements of interest.

3.4 Preconcentration (Extraction) Techniques

This method of concentrating environmentally important analytes from waters has been used extensively in XRF. Linder et al.\textsuperscript{(13)} Ellis et al.\textsuperscript{(8)} and Prange et al.\textsuperscript{(14)} used these methods for different types of XRF instrumentation. The method usually benefits from a single element, usually if not always iron, being present at relatively high concentrations compared with the analytes of interest. Thus the technique is often referred to as “coprecipitation”. The most effective method of coprecipitation uses the sodium salt form of dibenzyl dithiocarbamate (DBDTC). This carbamate form has been shown to achieve good recoveries for a wide range of analytes and their various valency states. A notable exception is the recovery of arsenic and antimony in the valency 5 state and Cr in the valency 3 state. However, for arsenic, Del Carmen et al.\textsuperscript{(15)} showed that the use of varying pH could achieve an analysis in both valency forms, thus providing valuable information on the more toxic As(III) form.

Coprecipitation techniques will produce a filter cake similar to those of the particulate filter method (see section 3.1) and thus can usually be quantified in a similar way. These will be discussed more fully in section 9 on method development.

3.5 Oxidation State – Speciation Using Preconcentration Methods

Most regulations require total element concentrations to be measured for quality control (QC) of prescribed elements. However, specific species of elements such as Cr, Se and As are far more biologically toxic than others. For this reason, speciation analysis can provide critical information for the environmental analyst. ICP coupled methods are ideally suited to this type of analysis in that they are capable of determining the different species within a sample. However, destructive sample preparation techniques such as acid digestion will remove this information so even the most ideal techniques can be limited for this type of analysis. In XRF, methods to determine speciation rely upon the sample preparation stage to separate species prior to analysis. This is carried out using pH control during the preconcentration stage of sample preparation and the selective use of appropriate concentration techniques best suited for the species required. This is best seen in Table 1, where the most useful element speciation methods are summarized.

requires all samples initially to be in solution form. Presentation of the sample to the spectrometer is by way of evaporation on quartz or Perspex® (Plexiglas®) supports. Thus dissolution methods are used as for AAS and ICP to provide a wide range of preparations. Table 2 gives a selection of studies using TXRF for the preparation of environmental samples.

Practitioners of TXRF have developed many techniques for the preparation of environmental samples, but they suffer from the same drawbacks of other dissolution technologies in that the sample sizes are very small and the methods have the potential for analyte loss. An important area of research and development with respect to TXRF is in the determination of metals in seawater.¹⁴ Analysis is based on the separation of the metals from any salt matrix and final concentration of trace metals as complexes using, for example, dithiocarbamate. Complexes are usually taken up in an organic media and pipetted on to TXRF quartz or Plexiglas® supports, where they are evaporated to dryness ready for analysis.

4 ENVIRONMENTAL APPLICATIONS

Applications for the analysis of liquids cover a broad field that can be broken down into a number of key areas:

- wastewater or nonhazardous liquid waste – i.e. industrial or domestic waste and agricultural muck used for land improvement; these can include sewage sludge, runoff or groundwater;
- LHW, i.e. aqueous and/or organic liquid; sludge or other samples potentially containing tens of percent solids.

4.1 Analysis of Natural Waters

Laboratory analysts typically require techniques capable of achieving detection limits 10 times lower than any regulatory limit. For potable water analysis, this requirement can only be achieved using a preconcentration technique when using conventional EDXRF or WDXRF. These techniques are similar if not the same as those used for preconcentration prior to using atomic spectroscopy techniques such as AAS and ICP. This analysis of essentially clean water includes river water, seawater and groundwater, the last from relatively noncontaminated sites.

There are two components that must be considered with respect to the analysis of natural water: suspended solids and dissolved elements. Requirements to determine the constituents of these two phases are often necessary. Particulate filtration of varying volumes of these waters using commercially available ashless filters will achieve the necessary concentration of analytes to allow direct analysis of the filtrates by XRF. A typical scheme for the preparation of samples for analysis of natural waters would be to filter 0.1–1 L of water through a series of
filters. The first filter to collect suspended particulates using a filter capable of trapping particulates down to 0.45 µm is followed by filters to trap dissolved elements using cation- and/or anion-exchange papers/resins.

This analysis regime has the drawback in that cation- and anion-exchange papers are pH sensitive. Section 3.3 describes the use of such filters. Practitioners are advised to seek the latest information from manufacturers of such papers to address any problems of pH sensitivity, paper capacity and known chemical interferences. The above regime using a series of ion-exchange filters does, however, leave some doubt as to what may pass through all of the papers. Elements not trapped (concentrated) on either the particulate filter paper or ion-exchange papers will be at very low levels. This leaves one area still to be determined using XRF.

Workers in this field\cite{8,13,14} conclude that the use of the preconcentration method using DBDTC gives the best overall performance for the extraction of metals from clean aqueous solutions. Subsequent reviews and studies have confirmed this conclusion.

Improvements in XRF technology and the introduction of the TXRF technique have made modifications to this method. Studies by Prange et al.\cite{14}, Stossel and Prange\cite{17} and Holynska et al.\cite{18} have refined this technique for use with TXRF.

Varshal et al.\cite{12} described a methodology for XRF analysis of natural waters using cellulose filters impregnated with conformationally flexible amino-carboxylic groups known as DETATA.

The analysis of seawater is treated as a special case. Owing to the high concentration of NaCl present, the metals must first be separated from the salt matrix using chromatographic techniques. Prange et al.\cite{14} described a technique for TXRF using chelation of the metals and selective chromatographic absorption of the metal complexes on lipophilized silica gel carriers with subsequent elution by chloroform–methanol mixtures. The final organic eluate is then dried on TXRF sample supports.

The analysis of natural waters is a key TXRF application. The use of WDXRF is restricted owing to the destruction of filters at high X-ray power typically used by such instruments.

Table 3 provides a review of the techniques that can be used for the analysis of natural waters in conjunction with XRF.

The majority of laboratories require instrument detection limits to be an order of magnitude below their working detection limit. Detection limits for preconcentration methods are difficult to assess owing to the range of XRF instrument configurations available. Concentration from volumes can vary from a few hundred to thousands of milliliters. The ultimate performance of any instrument and preconcentration method must therefore be based upon the minimum mass that can be detected on a filter, measured in micrograms present. Once this figure is determined then the volume required to achieve a measurement significantly above the detection level can be calculated. Figure 2 gives a summary of the typical range of detection limits quoted for XRF instruments. Note: where the literature uses a mass per volume measurement the data have been converted into micrograms present.

XRF instrumentation has improved over the years in terms of count-rate capability and computing power. The peak-to-background ratio that determines ultimate detection limits is controlled primarily by the sample matrix. For this reason, little improvement has been made in achieving lower mass detection limits on filter media since the first publications on these techniques.

### 4.2 Nonhazardous Liquid Waste

Nonhazardous liquid waste includes materials such as sewage sludge and agricultural sludge used for land improvement and industrial discharges to waterways. These materials are classified as nonhazardous, but they can contain high levels of heavy, potentially toxic metals, and therefore require monitoring.

Traditional methods of sample preparation used for sewage sludge or other materials containing high levels of organic matter are to dry and then ash at 500 °C to reduce the bulk and to concentrate metals for subsequent analysis. This process has a large drawback in that volatile metals such as mercury, cadmium, thallium, selenium, etc. can and often are lost in the process and that it can take many hours.

Direct analysis of sludge material requires first that the sample is homogeneous and that it will remain stable during the time of analysis. Sludge material is difficult to stabilize during the analysis times typically employed by XRF. The solid phase will often settle out during an analysis. However, for rapid qualitative scanning or quantitative screening this may not be a problem for heavier elements such as those required for monitoring.

For samples containing high levels of organic solids the sample preparation is usually as described in section 3.1. These samples can be split into two components, i.e. solid and liquid, with direct analysis of the solid and either direct analysis of the liquid or use of a preconcentration technique to achieve appropriate detection of the elements of interest. XRF provides a number of analytical schemes that can be employed for this type of analysis. The ability of XRF to measure samples in their "as-received" form provides some distinct advantages to the analyst.

Supernatant or liquid-phase and discharge waters can be treated using the scheme for clean water analyses but may have a high organic content which can cause interference. However, the requirement to achieve very low detection limits for this type of analysis is not as critical as it is for potable drinking and natural water. Direct analysis of the liquid phase will, in many cases, achieve an acceptable result. The liquid is placed directly into a liquid sample cell incorporating a suitable support film.

Nonhazardous waste in the form of solvents, oils and organic–aqueous mixed solutions often require analyses at very low total metal concentrations. For these type of analyses the preconcentration methods employed for aqueous solutions are not applicable. Organic liquids and solvents requiring determination at levels near or below the routine detection limit of XRF will need preconcentration. The use of chromatographic techniques such as liquid–liquid extraction can be used but in general this area of analysis is not an XRF application.

4.3 Liquid Hazardous Waste

Industrial needs for the measurement of LHW for both regulatory and disposal process monitoring requirements has led to the development of two dedicated XRF methods. Both methods were developed to provide cost-effective alternatives to more traditional ICPAES and AAS methods. These methods are promulgated through the ASTM and are designed to analyze fuel-quality waste (FQW) used principally in the cement industry and similar types of material. The methods are ASTM D5839(21) (approved in 1995) and D6052(22) (approved in 1997).

- The ASTM D5839 method is designed for the analysis of metals only in LHW that can be concentrated through the evaporation of the solvent/liquid fraction. A sample is evaporated to dryness and then mixed with high-purity carbon. Calibration is carried out using certified oil standards prepared in the same manner as unknown samples. Calibrations are linear for the concentration ranges required for regulatory and process control of LHW as an FQW. The method uses dilution into a common matrix, i.e. carbon, to achieve acceptable analytical performance. In this method carbon replaces the light element organic matrix, but the disadvantages of measuring heavy elements in a light matrix are still present and can make this technique prone to low recoveries owing to...

LLD, lower limit of detection.

- The ASTM D6052 method is capable of element determination from P to U. Using a <200-μm Al₂O₃ powder a LHW sample is mixed at a ratio of 3:1 (Al₂O₃ : sample). This mixture is then measured as a loose powder by EDXRF. Measurements are compared with a set of calibrations based upon traceable mixed-element standards as used for atomic emission/absorption spectroscopic calibrations.

The latter technique overcomes the principal problems that have historically limited the effective use of EDXRF in the analysis of liquids containing elements at highly variable concentrations in potentially multiphasic and/or turbid forms.²³

The principal advantages of the technique are summarized as follows:

- The Al₂O₃ is activated, with most elements determined, especially potentially volatile metals, firmly bound to the support matrix thus reducing the risk of analyte loss.
- The diluting matrix is relatively heavy compared with other matrices used in similar XRF sample preparation techniques, i.e. carbon²¹ and lithium tetraborate/metaborate.²⁴ This reduces infinite thickness problems in addition to reducing the spectral background.
- Calibrations are straight lines within the recommended concentration ranges, these being:
  - 0–5000 mg kg⁻¹ for metals;
  - 0–5 wt% for P, S, Cl;
  - 0–1 wt% for Br;
  - 0–2000 mg kg⁻¹ for I.
- Eliminates problems of phase separation and solids settling during analysis.
- The large sample size used, 5 g, increases representative analysis.

D6052 has been investigated by Piorek²⁵ for use in conjunction with a field-portable XRF analyzer. This gave results within the acceptable level of performance for a screening technique capable of field use, i.e. ±20% relative accuracy.

Table 4 shows the detection limits published for the D6052 technique.²²,²³ The analysis of LHW is an area that XRF has made many attempts to conquer. The concentrations of prescribed elements are often present at levels easily determinable by XRF. Two measurement techniques can be used to determine these elements:

1. Fundamental parameters (FPs) or standardless analysis. This technique is employed in all commercially available EDXRF and WDXRF instruments. It is based upon the characterization of a matrix in terms of its overall matrix composition and theoretical interelement X-ray line relationships. The XRF literature provides many examples of the use of FP; however, each instrument manufacturer has its own interpretation and exact method of set-up. Guidance from individual instrument manufacturers should be obtained in assessing the suitability of this technique for the elements of interest.

2. Calibrations using certified aqueous and organic/oil standards are the favoured technique used with the standard methods described above.

4.4 Environmental Samples Related to the Nuclear Industry

The determination of long-lived radionuclides and those of low energy, such as uranium, plutonium, thorium and technetium, have been reported to be suitable for analysis using XRF. McMahon²⁶ describes the various merits of different XRF instrumentation for their analysis.
4.5 Novel Applications

The use of XRF in the analysis of environmental samples is one of practical application. Most researchers use or have developed techniques that can be readily applied. Of a more esoteric nature is the use of synchrotron radiation with EDXRF and the use of energy-dispersive X-ray (EDX) analysis with microprobes. Kaplan et al.\(^{27}\) used synchrotron excitation EDXRF and EDX to study the transportation of metal contaminants held in the mobile-solid (colloidal) phase within interstitial pores between particles of soil from a contaminated site. The techniques used provide further examples of environmental application of XRF although few researchers have access to such facilities.

Ultrathin-film supports (0.15 \(\mu\)m) have been developed for the analysis of parts per billion levels of elements in small samples (5–50 \(\mu\)L).\(^{28}\) This method is applicable to very clean aqueous solutions containing no more than 100 ppm total element content (Na–U), hence its usefulness in many environmental applications is limited.

5 INTERFERENCE

Interference present when using methods of preconcentration or advanced methods of preparation, i.e. not “as-received” type analysis, can be separated into two main areas: chemical interference which occurs during the preparation of the sample and instrumental interference that is specific to the XRF technique.

5.1 Chemical Interference

Chemical interference usually occurs owing to the inability of all elemental species present within a sample to be quantitatively extracted/concentrated under a single pH regime. Techniques cited in this article provide information on the selectivity of elements and their species, in addition to typical recoveries achieved from the analysis of real samples. Sample preparation methodologies cited detail those elements and valency states that are not selected owing to incorrect pH or other reasons.

Depending on the method employed and the element range to which it is suited, any chemical interferences described in the literature must be accounted for. The main influences or limitations are due to pH. It is generally not possible to recover all valency forms for the range of environmentally sensitive elements in one preparation. Although some preparations are more specific and will capture (recover) differing sets of elements, it is recommended that methods providing a wide elemental selectivity be used. Tables 1–3 show preparation methods and a range of elements and valency states each is capable of selecting.

It is not possible to give a complete listing of influences observed using ion-exchange papers as these are continuously being improved. Any practitioner selecting methods of preconcentration using ion exchange should obtain advice and information from instrument manufacturers and suppliers of such exchange papers. Information provided by manufacturer product listings should be independently verified prior to use.

5.2 Instrument Interferences

Instrument interferences are those that occur between elements at the atomic level, i.e. interelement, or as a limitation of the instrument used to separate and quantify the individual element data from an XRF spectrum. Interelement effects are of two types, absorption and enhancement. The dominant effect is absorption. The majority of instrument manufacturers provide details on these influences and tables or software to show their relationships. Figure 3 shows a spectrum of Cd, Sn and Te and the Cd absorption edge position. In this example Cd is capable of absorbing Te as its absorption edge is just below that of Te K\(\alpha\) lines; however, Cd will only absorb Sn K\(\beta\) as its K absorption edge is between that of the two Sn K series lines. For trace element analysis in waters these interelement influences are usually very small and can be ignored. When using filter papers the sample can be considered as being infinitely thin, i.e. the corrections required are based on thin-film techniques where absorption and enhancement effects are also considered to be negligible. Thin-film techniques assume no or insignificant interelement effects. These effects are

---

**Figure 3** Interelement effects.
applicable to all XRF techniques, i.e. WDXRF, EDXRF and TXRF.

There are a number of ways in which data can be extracted from EDXRF spectra:

- Using a region of interest (ROI): this technique is suited to elements that are not overlapped by others, or the overlap is minimal. This method of data extraction is the most accurate and will give the highest precision of measurement. For more complex spectra, using a set of regions and overlap factors, data can be extracted. This is similar to the use of ROIs, but will allow more complex overlaps to be resolved. However, highly complex spectra where many overlaps exist will be poorly resolved when using this type of spectrum processing.

- Pure element spectrum lines: pure element spectrum lines are used to fit to a spectrum using various peak-fitting mathematical models, e.g. least-squares fitting. This process requires the setting up of the instrument with a set of pure element spectra, either measured from real samples or computer generated. Each line will be needed to fit to the spectrum to allow deconvolution to work. This method potentially will give the best element resolution of highly complex spectra. The precision of measurement is in both cases (ROI or element spectrum), influenced by the number of overlaps being corrected or the element lines active in the spectrum processing. Pure element spectral lines for L series spectra will need to be made from thin-film samples if they are to be used on filters. Variations in interline sensitivities between thin and bulk samples will change. For this reason, many manufacturers supply spectral lines that are split into their sub-line series, i.e. Lα, Lβ, Lγ series.

For EDXRF instruments, the main interference is spectrum line overlap. This occurs when one element's line series overlaps that of its neighbors, or a low-energy line series of a heavy element overlaps the line series of a lighter element, e.g. L line overlapping K line spectrum. Figure 4 shows an example of this problem using the classical As Kα and Pb Lα line series overlap. Modern spectrometers use complex mathematical spectrum deconvolution algorithms to extract data from a spectrum. Owing to the use of mathematical algorithms, errors in spectrum processing can be high. The greater the spectrum line overlap, the greater the potential error will be.

WDXRF uses either scanning or fixed monochromators. For fixed-channel systems (simultaneous), the spectral information can only be corrected for overlap if the overlapping element is also present as a fixed-channel. For scanning instruments (sequential), extra scanning points can be programmed to measure overlapping elements and overlap factors applied.

6 ANALYSIS TECHNIQUES

XRF provides two ways of quantification. The first uses a suite of matrix matching standards to produce a calibration line for each element of interest. The second uses a technique specific to XRF referred to as FP or sometimes known as standardless analysis.

6.1 Calibration Techniques

Calibrations can be formed in two ways. The first is to select a group of standards to cover the range of matrix variation and element concentrations to be determined. This can often result in many standards being required. For environmental samples/standards these are often not available. Other methods of producing standards have been used; these are based on methods used for other instrumental techniques, e.g. standard additions, spiking real samples and producing synthetic standards with matching matrices.

Another form of standards calibration is to reduce all standards and samples to a common matrix form. This is essentially what is carried out for atomic emission spectroscopy when samples are usually reduced to an aqueous phase. In XRF the requirement to digest a sample is absent. Instead, a sample can be mixed with a solid medium and either fused into a glass bead or mixed in some way to form a powder. The advantage of these latter forms of standards calibration is that synthetic standards can then be employed widely with no matrix variations existing between standards and samples.

The analysis of environmental samples demands a lot of thought from an analyst. In terms of waste, by definition,

Figure 4 Spectral overlap.
there is no such thing as a standard waste. For this reason, the analyses of waste materials requires calibration to be carried out on samples that can be reduced to a common form. In the last 5 years a number of methods have been promulgated to provide the analyst with ways of calibrating XRF instruments for the analysis of a wide range of liquid waste matrices.\textsuperscript{(21–25)}

Any analysis carried out using these methods should be validated on the basis of final data quality objectives (DQOs) using protocols formulated by organizations such as the USEPA and ASTM. The determination of volatile toxic metals should be given great emphasis when deciding on a method of sample preparation. Any heating of the sample must be considered as a possible source of analyte loss and should be avoided.

Matrix correction techniques used in XRF are shown below. Different manufacturers of XRF instruments provide different solutions depending on instrument geometry. The discussion below attempts to provide an overview of the available techniques used:

1. measurements of high-energy background (Compton);
2. reduction of background using polarized X-rays;
3. use of constant mass for samples;
4. use of internal standard.

One of the most common methods of matrix correction is the measurement and subsequent ratioing of an analyte line to the characteristic Compton $K_a$ line in the spectrum. The Compton anode line is generated by the scattering of the X-ray tube anode lines (present in the primary excitation spectrum generated by the tube) scattering off the sample and being detected in the detector. This scattering process is one of energy loss, thus the Compton tube anode line is observed in the spectrum at a point of lower energy than that of the anode energy. The magnitude of the Compton peak is inversely proportional to the average density or atomic weight of the sample. The gross integral Compton line can be used to correct for matrix effects from the position of the Compton line down through lines in lower energy until the first major element line is reached. In many matrix types this is usually to the iron absorption edge at 7.11 keV.

Using polarization to reduce background is highly beneficial in achieving low detection limits for low-Z matrices and improving spectral processing. A drawback, however, is that matrix information is present in the background and matrix correction is still required. Therefore, instruments employing polarization must generate an “extra” spectrum with background, preferably a Compton peak. Typically these instruments require higher power X-ray tubes producing 200 W−2 kW.

In order to reduce the number of parameters which will influence an XRF analysis, samples with low-Z matrices or samples that have varying densities should be weighed to a constant mass. This is particularly important where elements are to be measured in matrices that do not provide infinite thickness with respect to the analyte lines of interest. Figure 5 demonstrates the problem of infinite thickness. The use of constant mass is particularly important when calibrations are to be used.

The use of an internal standard at constant mass relative to the mass of sample is a well-known technique for the correction of matrix effects. This can be particularly useful when dealing with low-Z analytes where obtaining sufficient intensity for background measurements in this region of the spectrum (1−5 keV) is more difficult. A number of international standards for the use of XRF employ this technique (e.g. ISO 14596 for the analysis of S in petroleum products).

When using WDXRF simultaneous instruments, although this type of instrument is unsuited to general environmental analysis, a Compton background channel should be fitted where wide matrix variations are expected.

EDXRF and WDXRF can also employ empirical and theoretical “alpha” models based on measured intensities and standard concentrations, respectively. These are used to correct for interelement effects where the matrix is relatively well defined in terms of the major elements and where sufficient standards are available.

![Figure 5](image-url) Infinitie thickness. The sample is infinitely thick with respect to Fe but not Cd, i.e. the sample is capable of absorbing Fe but not Cd.

6.2 Fundamental Parameter Techniques

Most conventional EDXRF and WDXRF manufacturers provide methods for the analysis of “unknown” samples by means of semiquantitative FP analysis. It is only possible to provide general considerations on the use of this technique as different manufacturers have distinct setting-up requirements and limitations.

Unlike using calibration standards, FP require no matrix-matching standards. However, for FP to calculate all the effects that each element has on another, knowledge of the complete sample matrix is required. As the name suggests, FP relate the physical XRF excitation and detection characteristics of an instrument to the theoretical interelement affects within a sample. This creates a relationship between measured fluorescence intensity of an element in a matrix and its concentration. With the application of corrections such as Compton and/or Rayleigh scattering ratios, for nondetected matrix effects (i.e. organic or aqueous components) a final concentration for each element can be determined. For this reason, the major composition of a sample must be defined either in terms of elements present and/or as a balance. The balance is usually the organic or aqueous component not detectable by XRF.

6.3 International Standard Methods

Table 5 gives a list of the currently available internationally recognized standard reference methods used for the determination of various elements by XRF in liquid matrices for environmental monitoring and regulatory compliance.

Standard methods for the analysis of S and Pb in petroleum products are covered by a series of methods, some of which are prescribed through legislation as mandatory in some countries. Although these methods do not necessarily come under the umbrella of water or wastewater they are designed to ensure that petroleum products meet local environmental legislation and thus are included in this article. All the petroleum methods use calibration techniques of ratio to a background and some, as in the case of ISO 14596, include an internal standard element. These methods are not designed for the analysis of waste material and should not be used for that purpose. Details of the method requirements should be obtained from the appropriate organization.

7 REGULATIONS

Regulations governing the disposal, use and monitoring of waters and wastewater differ from one country to another. For each main section described in this article, i.e. natural water, nonhazardous liquid waste and LHW, different regulations apply.

7.1 Natural Water

The regulations are principally concerned with final drinking water quality. Therefore, this article will concern itself only with those regulations. Any practitioners carrying out analysis of such water should consult their local authority for up-to-date information. Table 6 describes the regulations currently used by the USEPA. This does not represent an exhaustive list of elements but provides an outline of elements required for determination and some typical concentration levels required. Different quality criteria will be used for different world wide and cross-government authorities [e.g. World Health Organization (WHO) and European Environment Agency]. In general, only TXRF is suitable for the routine analysis of natural waters (including potable drinking water).

7.2 Nonhazardous Liquid Waste

Two areas of analysis need to be considered:

- disposal: this may be into a local river or into the sewerage system;
- the monitoring of such systems.

7.3 Liquid Hazardous Waste

This area of analysis can also be split into two areas:

- one of assessing the toxicity of any hazardous waste;
- deciding on a suitable disposal route.

The choice of disposal route requires that waste will meet both legislative requirements in terms of maximum...

emissions but incineration facilities use in-bound fuel specifications to control this process. Table 8 shows a list of typically controlled elements and an indication of regulatory concentration levels. The actual control of elements within this category is based upon their disposal route. LHW use as a SLF is controlled under a user licensing system in the UK and Europe, the contents of which are usually commercially sensitive. Disposal through high-temperature incineration for highly toxic LHW is controlled, from the regulatory standpoint, through stack emission monitoring and individual licensing depending on the capability of the facility. Underground liquid injection, where permitted, is controlled by specific local legislation.

A listing of environmental agencies and their Internet World Wide Web sites is shown in Table 9. These sites offer a range of information and are excellent sources for first contact points in obtaining the latest details and data about local issues and legislation.

8 QUALITY CONTROL AND TROUBLESHOOTING

QC of methods used for the analysis of environmental samples should follow standard good laboratory practice (GLP) guidelines as used for any instrumental analysis technique. Any method developed should provide a history of validation based upon DQOs. The DQO will vary according to the methods usage, i.e. regulatory control, screening only, process control and analytical performance requirements. The use of DQO strategies is described in standards developed through organizations such as the USEPA and ASTM. These are very large documents covering the complete range of waste management activities. Practitioners should limit their research to those sections that define the analytical requirements or capability of a method they wish to employ.

XRF instruments are intrinsically stable when compared with other multielement instrumental techniques. Calibrations are developed as a “one-off”, with recalibration often not required for years. For this reason, QC requirements are based mainly around establishing and maintaining sample preparation and presentation criteria.

In general, methods developed for use on XRF instruments require two forms of QC monitoring:

1. The instrument should be shown to be stable prior to measurement of any sample. This is carried out by the measurement of a QC monitor. This measurement must be carried out using the same instrument conditions as used for the sample. Comparing the QC monitor concentration with that of the time of calibration (day zero) is usually sufficient to confirm stability. This type of measurement is usually carried out on a daily or shift basis.

2. Using a blank sample and a suitable, either synthetic sample (of known composition), or standard, prepare real samples for analysis. Performance of the blank and “standard” in terms of the DQO for each element will confirm the method’s suitability for use. These types of measurements are usually carried out on a weekly basis.

If a measurement fails any QC requirement then a number of checks can be made. The following is a brief outline of some of the most commonly occurring problems that can occur assuming the sample has been reanalyzed and freshly prepared to check for obvious errors:

- When using an autosampler, check whether the sample was correctly positioned and measured.
- Check any diagnostic evidence reported with the analysis, e.g. high instrument detector resolution, unusually high errors of analysis, for EDXRF spectrum processing giving poor fitting, indicating a failure of a detector component.
- Sample chamber atmosphere not set correctly, e.g. He gas not turned on or empty cylinder. Observed as a low count rate for light elements but correct for higher Z elements.
- Contamination on X-ray tube or detector components. Observed as a low count rate but all other diagnostic information satisfactory.

For analyses that give results differing from those provided through either standard organizations or from analysis by other techniques, the following tests should be carried out:

- For FP methods a comparison of the elements specified in the analytical method and those observed qualitatively must be made. If a major element, not specified in the method, is observed then it must be added and the sample reprocessed where possible. This indicates that further method development should be carried out.
- When poor detection of minor or trace elements occurs in an EDXRF spectrum, check for the presence of an unexpected major or minor element, not originally specified in the method. This is usually observed by degradation in spectrum processing. This indicates that further method development should be carried out.
When poor detection of minor or trace elements occurs in a WDXRF spectrum, check that minor or major element spectrum overlaps of trace elements are capable of being resolved by the diffraction crystal used in the monochromator or goniometer, e.g. Ba on Ti or Pb on As. Add any overlap corrections as required in the method. This indicates that further method development should be carried out.

Observation of elements not expected to be present. When measuring low-Z matrices and thin samples such as filters, the high background scatter and poor stopping power of the sample may on occasions excite some of the metals or materials used in the construction of the instrument or any sample holder, e.g. Cu and Zn from brass or bronze and Cr, Fe or Ni from stainless steel. These minor impurities or contaminants can be eliminated by the measurement of appropriate blanks. Consideration of this issue is particularly important for thin samples and those of insufficient infinite thickness.

The result of a measurement is shown to be incorrect.

- For calibration methods this may occur if a matrix correction is not appropriately applied. The sample is of a sufficiently different matrix type that the calibration used is inappropriate – this will be apparent if major element and especially Compton peak count rates compared with the calibration are outside the calibration range.

- For FP analysis the stoichiometry should be matched to the sample. Mixed stoichiometries such as the presence of metal chlorides and oxides or carbonates and oxides are difficult to resolve and can lead to inaccuracies if a metal were present in the chloride form but specified in the method as oxide. Non-detectable elements such as C, H and N present as CO₂, H₂O, etc. need to be calculated using matrix correction procedures such as Compton–Rayleigh ratio or entering information provided from other measurement techniques.

9 METHOD DEVELOPMENT

The development of a method will be dependent upon the type of instrument and the instrument manufacturer’s recommendations. The three main types of instruments referred to in this article, i.e. EDXRF, WDXRF and TXRF, require different strategies. The development of a method is split into two components, the sample preparation and the set-up of the instrument – the latter will depend upon the manufacturer’s recommendations and type of instrument.

9.1 Energy-dispersive X-ray Fluorescence

Four types of system are in use today:

1. direct or filtered direct excitation of a sample with detection using an Si(Li) detector;
2. direct excitation of different metals targets to produce a secondary excitation to excite the sample with detection using an Si(Li) detector;
3. scattering crystals to produce polarized primary beam excitation with combinations of secondary beam excitation and Bragg reflection crystals to optimize peak-to-background performance using a detection system similar to those above, i.e. Si(Li) detector;
4. either isotope sources or low-powered X-ray tubes with a combination of primary and secondary beam filtration and a sealed gas proportional detector or for hand-held field analysis a silicon PIN diode semiconductor.

Si(Li) detectors are of two main types: those which use liquid nitrogen for cooling and those which do not. Of the latter a number of different types are available, the most common using a Peltier cooled detector. Other types are available but at relatively high cost, e.g. those that use the Joule–Tompson effect for cooling or a Stirling engine. EDXRF uses a number of key parameters to optimize the excitation of elements within a sample and their subsequent detection. The main components are as follows:

- X-ray tube, anode types of Rh, Ag, Pd, Mo being the most common;
- primary beam filter placed between the tube and the sample;
- secondary target placed between the tube and the sample;
- polarizing crystal scatterer placed between the tube and the sample;
- Bragg reflector between the sample and the detector;
- type of detector – Si(Li), PIN diode or gas (Ne, Ar, Kr or Xe) filled proportional.

The key parameters and combinations used are shown in Table 10. Depending on the combinations of tube anode excitation voltage (kilovolts) and primary beam filtration, different ranges of elements can be excited. In general the following rules of thumb can be used to classify elements into ranges of instrument excitation parameters. For all forms of EDXRF the following general rules will apply:

The excitation and subsequent detection of $Z$ conversely, high-$Z$ matrices produce little background scatter. The excitation and subsequent detection of high-$Z$ elements in low-$Z$ matrices is very efficient. Achieving the best detection limit requires minimizing the scattered background produced by the low-$Z$ matrix and maximizing the sensitivity of the high-$Z$ element(s) of interest.

The sensitivity of heavy (high-$Z$) elements in liquid matrices is dependent upon the density and thickness of the sample measured. The infinite thickness of a sample with respect to the X-ray lines of the elements of interest, must be controlled or in some way measured in order to obtain reliable quantitative analysis. Figure 5 and Equations (1) and (2) show the effect of varying infinite thickness or sample depth (thickness) and its potential affects on quantitative results. In Figure 5 it is clear that the sample can absorb Fe K but not Cd K X-rays (i.e. Cd K X-rays are capable of passing through). This is referred to as the infinite thickness of a sample with respect to an element. To measure quantitatively the amount of Fe and Cd present in the sample it is important to realize that the effective volume or, as the diameter of a sample is usually constant, thickness of sample measured by the detector for each element is different. This is due to the different energies of the fluorescence X-rays emitted from each element. The effective volume/thickness of sample measured for each element is controlled by the density of the sample matrix and its ability to absorb characteristic fluorescence X-rays from the elements present. If the potential volume/thickness that an element can be measured from is greater than the volume/thickness of sample then the relationship between fluorescence measured and element concentration is no longer constant. The fluorescence measured will increase up to the point of infinite thickness for each element present. Therefore, if a sample is not infinitely thick with respect to the elements of interest, errors will occur in any quantitative measurements.

Equation (1) defines the relationship between infinite thickness and analyte element:

$$I = l_0 e^{-\left(\frac{t}{\mu}\right)}$$

where $I$ is the absorbed radiation, $l_0$ is the incident radiation, $\mu$ is the mass absorption coefficient, $\rho$ is the matrix density and $t$ is the matrix thickness.

For practical purposes this equation can be solved for $t$ to show the following form (Equation 2):

$$t = \frac{6.9}{\mu \rho} \sin \theta$$

where $\theta$ is the takeoff angle between the sample plane and the detector.

The effects of infinite thickness are of particular importance to the analysis of low-$Z$ matrices such as water, wastewater and LHW. The majority of elements...
of interest for environmental analysis in waters and wastewaters are those of the transition metals and elements with $Z > 30$. The typical volumes of sample measured in spectrometers are in the region of 5–15 mL. These samples are presented to the instrument in sample cups of typical height less than 3 cm. In these matrix types the transition metals and heavier elements are not infinitely thick with respect to the solution matrix. The presence of lighter elements such as the alkaline earths and dissolved calcium reduces the infinite thickness for the typically required environmentally sensitive elements. However, it is often the case that samples presented in this manner will require some measurement that relates infinite thickness (or lack of) to that of the concentration of heavy elements present.

For samples where infinite thickness is a problem the following techniques of sample preparation can be employed:

- Weigh samples to a constant mass into sample cups. This is a particularly useful technique especially if samples vary in density.
- Add an internal standard (element). The element chosen must be affected by the matrix and infinite thickness problems in the same way as those elements to be determined. A downside to this technique is the additional stage required and that, typically, elements that can be used are elements of possible interest.
- Reduce the sample size such that the effect of infinite thickness is of no consequence. Typically, a thin layer of sample is used. This can be useful if the sample size available is very small; however, the sensitivity for elements of interests will be significantly reduced. High-energy background in the range 20–50 keV will dominate spectra where the sample is supported by a low-$Z$ matrix, e.g. cellulose filter paper. This limits the method unless instruments are equipped with features that reduce this background component, e.g. polarized X-rays. Counting times will need to be increased to overcome reduced sensitivity.
- Add a heavy element to reduce infinite thickness – referred to as adding a heavy absorber. This is similar to above but the amount used is significant and will dilute the sample by a factor of two or more. This will reduce sensitivity and degrade detection limits. This method is better suited to WDXRF than EDXRF instruments.

For samples where infinite thickness is a problem the following instrumental techniques can be employed:

- Calculation of effect of infinite thickness by inclusion of sample thickness in the analysis equations. This is of particular importance if an FP method of analysis is used.
- Measurements of a section of the spectrum that can be used to correct for lack of infinite thickness, e.g. X-ray tube Compton and/or Rayleigh lines.

The effects of matrix-induced background can be controlled by both sample preparation techniques and instrumental components. The only method of sample preparation used to reduce the effect of background scatter is to add a heavy element to the sample. This has the effect of reducing background scatter and infinite thickness depth with respect to heavier elements that may be required for analysis. This does, however, add complexity to the sample preparation and reduces the measuring precision owing to the errors associated with the additional stages of preparation.

Recent improvements in EDXRF spectrometer design have come from a need to reduce the background component. This has led to the development of devices to reduce both background beneath spectrum lines and high-energy scatter. A number of papers describing spectrometers using these devices have been published, e.g. by Yokhin and Tisdale, Haschke et al., and Heckel. As the detection limit requirements for environmental analysis are being pushed lower, this area of research has been shown to produce the most benefits. The effect of using such devices is to maximize sensitivity and minimize background. Using a polarized primary beam, the background present under an element peak can be reduced with no significant sacrifice to the sensitivity as long as sufficiently high-powered X-ray tubes are used. Heckel used a primary beam scattering device to “focus” excitation close to elements of interest, thus increasing the sensitivity over a narrow region of the spectrum. This reduces the amount of unwanted X-rays (usually background continuum) entering the detector. Thus detectors of moderate count-rate capability can be used efficiently for the collection of spectral data, i.e. for those elements of environmental interest.

- For EDXRF instruments, increasing the power of X-ray tubes or the count rate of detectors will improve detection limits, but usually at a financial cost and only by small increments. For any increase in X-ray tube power, a corresponding improvement in the detection system is also required. This is a consequence of using one detector, having a finite count-rate capability, to collect all spectral data. In general, one element cannot be selectively detected differently from its neighbors.
- For WDXRF, elements are detected selectively. Detectors are capable of millions of counts per
second, so at detection levels this performance is not limiting. Simply increasing the count rate by increasing the X-ray tube power will have a corresponding effect on the LLD, i.e. doubling the count-rate will produce a $\sqrt{2}$ improvement on LLD. Typically increasing X-ray tube power is not difficult or financially a burden for this type of instrumentation; however, sample damage or destruction will occur if the tube power is too high and will ultimately be a limiting factor.

For analysis of environmental samples using WDXRF, the sequential instrument is generally the one chosen. This is due to the number of elements required and provides the maximum flexibility. Presentation of the sample to these instruments must be done with care when using “as-received” liquid or semiliquid samples. Reliance on a thin X-ray film to support these types of samples must be a consideration when using high-power excitation conditions. Unlike EDXRF, WDXRF instruments are very difficult to clean if a sample should leak into the sample-measuring chamber. WDXRF instruments are provided with safety windows to minimize liquid spilling into the spectrometer.

**9.3.1 Choice of Sample Support Films**

There are many support films commercially available and also films supplied by individual XRF instrument manufacturers. The choice of film is based upon two criteria:

1. elements to be determined;
2. chemical resistance required.

Unfortunately it is often the case that these two requirements are mutually exclusive; however, for typically required environmentally sensitive elements, i.e. $Z > 20$, a polyester-based film is clearly suitable. This type of film is available through any XRF consumable supplier and a number of instrument manufacturers in various thicknesses (usually 4–6µm) and sizes.

Where light elements are required, e.g. P, S and Cl, a polyester-based film has some drawbacks:

- the oxygen content of such films attenuates the X-ray beam;
- the film produces a high background.

In this case a polypropylene film provides superior X-ray transmission and lower background over polyester and is chemically resistant to most aqueous and organic solvents encountered. However, experience has shown that leaching of halogenated solvents through polypropylene film will occur, especially for aromatic compounds.

This is usually seen by a relaxation and crinkling of the film, which is exacerbated as the temperature within the sample chamber increases. The general-purpose use of this film is not recommended for this reason and because it is significantly more expensive than any other.

Before a sample support film is used it should be assessed. Leaving a sample supported by the film, on blotting paper, for not less than its expected residence time in the sample chamber will confirm its suitability. If the sample leaks, as evidenced on the blotting paper, then an alternative film must be used. It is necessary to evaluate all possible sample types before making a final choice as a change of film may invalidate a calibration. Instrument manufacturers and suppliers of X-ray sample support films provide valuable information on the suitability of films.

**9.3.2 Calibration Methods**

Where elements can be detected at measurable levels within natural and wastewaters, and generally in the analysis of LHW, a method using a set of calibration standards can be employed. This is usually restricted to the analysis of LHW, as the lower limits of quantitation are relatively high. Direct “as-received” analysis of natural and nonhazardous wastewater often requires limits of quantitation below the detection limit of the technique.

Pure and mixed analyte calibration standards are available through any reputable chemical supplier. These can be used to produce a synthetic set of standards to calibrate a spectrometer. For simple matrix types such as river water or nonhazardous liquids, only waste calibration standards can be used, with an appropriate correction for matrix variation such as infinite thickness.

For the analysis of LHW, synthetic calibrations based upon pure or mixed analyte standards are rarely satisfactory. The methods developed under the auspices of ASTM, e.g. D6052 and D5839, should be used.

Filter cake material present as solid residue from industrial filters and pressed into pellets can be measured against a calibration. Typically this uses soil and other geological standards. Calibrations should be set up to correct for interelement effects and provide a means of correcting for overall matrix effects using a ratio to Compton peak for elements in the Fe–Mo (K series lines) and Pr–Bi (L series lines) range. Practitioners requiring this type of analysis are advised to treat samples as soils and review those XRF methods that apply.

**9.3.3 Fundamental Parameter Methods**

The analysis of LHW, using the FP approach, has been shown to be successful by a number of manufacturers.
This relies on an accurate measurement of the sample matrix, typically organic, using proprietary software and instrument-specific algorithms. The ultimate performance of such techniques is still a matter for some debate within the XRF scientific community. The use of this technique is clearly an advantage where standards cannot be synthesized or obtained. The speed and adequate detection limit capability of XRF for the measurement of LHW have already made this method of analysis acceptable within an industrial environment. The ±20% accuracy requirements for LHW make the use of FP almost ideal for their analysis. When using FP analysis for LHW samples it is important to specify stoichiometry. For the analysis of most liquids and sludges it is usual to represent all elements in their elemental form. The balance or mean Z of the matrix is then represented as H₂O or C. However, for “as-received” samples, settling of particulates and separation of multiple liquid phases during analysis will remain a problem and limit the success of any such measurement. The analysis of filter cake in the form of pressed pellets or dried solid requires a different approach to FP analysis. These sample types are usually given a stoichiometry for the major elements as stable oxides. The water content is then determined by ashing and added to the analysis as a fixed H₂O content. The benefit of separately determining the water content is that the errors produced within an analysis due to the need to estimate the nondetected H₂O fraction are removed. The sample is measured “as-received”, thus avoiding potential volatile element losses.

The ability to re-process XRF data to obtain more accurate results after the addition of non-XRF detected element data is a method that can be used in a FP analysis. The use of the FP approach for natural and nonhazardous wastewater analysis is of little appeal. Performance criteria make such methods difficult to validate and with the ease of producing standards for use in calibrations, FP analysis for such matrix types is of little use.

9.4 Analysis Using Total-reflection X-ray Fluorescence

Unlike conventional EDXRF, TXRF relies on no interelement effects existing. For this reason, conventional bulk sample FP-type analysis is not applicable. Once the liquid sample/standard is dried on the analysis support (quartz or Perspex/Plexiglas™), all samples will appear essentially the same to the instrument. Calibrations are developed using internal standards.

The reasons for addition of an internal standard during sample preparation are twofold, first to ensure that the sample recovery is within acceptable levels and second to act as a reference point for sensitivity corrections and subsequent concentration calculations. A reference point element, typically Co for transition metals analysis, is used in the following way:

- The sensitivity relationship between the reference element and neighboring elements measured under the same instrument conditions is precalculated, usually as part of instrument setting-up routines.
- The intensity versus concentration relationship of the reference element is defined in terms of the original concentration in the sample, often micrograms per kilogram or parts per billion, not its concentration or mass on the support. When measuring a sample containing the reference element it is then possible to calculate the concentration of the other elements present using the sensitivity information.

The above scheme allows complex samples containing many elements to be measured without the need to provide large numbers of standards.

9.5 Analysis of Filters

Using the filters prepared in any of the ways referred to in section 3, conventional EDXRF or WDXRF can be employed to carry out the final determination. Using a set of conditions such as those described in Tables 10 and 11 or as recommended by the instrument manufacturer, the environmentally sensitive elements can be measured.

As the samples are relatively homogeneous and of the same dimensions (i.e. the same filter papers are used for all measurements, typically 25- or 47-mm diameter) analysis is carried out by reference to a calibration developed from a set of reference standards. Standards can be either purchased through standards reference organizations, of which a selection of those providing environmental standards are shown in Table 12, or manufactured to individual requirements.

Using certified standard solutions (purchased through any reputable chemical supplier) containing the elements of interest at concentration levels that can be preconcentrated on the filter medium used, a series of standards can be made. First a series of solutions containing a mixture of the elements required is produced. These solutions are then preconcentrated using the technique chosen for sample preparation. The concentrations of the solutions used should be such that when preconcentrated on the filter the series of filters will hold masses for each element that will span from the detection limit to an estimated value representing the highest mass expected. It should be noted that the sample volume used can be varied to provide higher levels of preconcentration if lower levels of detection are required.

Standards prepared from solution should be tested for extraction recoveries before using. This can be done using

radiotracers as described by Prange et al.\(^{14}\) or through calibration validation using certified water standards.

Typically the filtered area of paper is kept as small as possible but not so large that the filtrate mass will build up to produce interelement effects within the sample. Typically masses in the tens of milligrams range spread over 25–47-mm diameter filters should not be exceeded.

Calibrations are linear across the range of concentrations required for this analysis. Corrections for any interelement effects are not required.

The analysis of unknown samples must include volume data. The analysis of a filter will produce mass data. If the volume of the sample is the same as the volume used for calibration, then the result is directly comparable, e.g. 100 µg measured on a filter will equate to 100 µg/volume of calibration standard. If the volumes of calibration standards and samples are different, then the measured sample mass must be divided by the sample volume. This will provide a corrected concentration in terms of mass/volume.

When measuring filter papers it is vital that both the area excited by the X-ray beam and that seen by the detector cover the filtrate. Failure to achieve this would result in lower than expected count rates for the elements present and thus low recovery figures.

Filters must be held in such a way as to ensure that the entire filter surface is measured. It is often the case that the sample is not homogeneously distributed across the filter. As the cross-section of the X-ray beam does not have a uniform field of flux the excitation efficiency will vary. For this reason it is routine to spin filter samples, thus ensuring that the variations in filtrate density and X-ray beam flux are normalized. For filters larger than the X-ray beam a spinning mechanism that rotates the sample offset from the X-ray beam is required. This will ensure that the entire surface of the filter is covered, producing an average signal. Variations in filtrate density are equally accounted for using an offset spinning mechanism.

The only correction required for filter analysis, assuming the filtrate mass does not generate significant interelement effects, is a ratio to Compton for elements in the Fe–Mo K series lines) and Pr–Bi (L series lines) range. This will correct for variations in the overall matrix.

For the analysis of elements with \(Z > 20\) (Ca), an air path environment can be used with EDXRF. WDXRF requires vacuum or for \(Z > 20\) a helium atmosphere if samples are to be measured “damp”.

10 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

10.1 Comparison of Technology

Two main techniques, AAS and ICPAES, dominate elemental analysis. XRF competes with ICPAES for the analysis of environmental samples for the appropriate analysis of elements with \(Z > 11\). Ion chromatography (IC) for the analysis of S and halogens is also widely used in environmental analysis and is particularly used for fluorine analysis in liquid samples for which XRF is not suitable.

ICPMS is used for ultratrace-level analysis (micrograms per kilogram), particularly of potable drinking water; however, this level of performance is not required for nonhazardous and hazardous liquid waste. TXRF provides comparable performance although it is limited to the analysis of elements typically with \(Z > 20\).

An advantage over spectrophotometric methods such as AAS and ICPAES is XRF’s ability to measure the halogens and S in addition to prescribed trace contaminants such as heavy metals. In LHW materials halogens and S compounds are common. At the levels of analysis required by industry for incinerator process control or determining disposal routes, XRF provides a rapid semi-quantitative to quantitative method for S and halogens.

Pedersen and Higgins\(^ {37}\) and Kendall et al.,\(^ {38}\) showing comparisons of EDXRF versus IC, ICPAES and AAS (flame and furnace) techniques for the analysis of
LHW, demonstrated the advantages in using EDXRF methodologies for the regulatory and process control conformance analysis of FQW.

The remaining environmentally sensitive elements not able to be determined by XRF in liquid samples, i.e. Be and B, will drive laboratories to continue to use AAS, ICPAES and ICPMS. However, the cost savings and speed of analysis provided by XRF will tend to minimize the need for every sample to be measured for these light analytes.

Where XRF has a role to play is in the rapid routine analysis of toxic LHW where levels are high enough to perform close to “as-received” analysis and still provide analytical techniques that will allow one-off measurements of clean and nonhazardous liquid waste and water.

The analysis of halogens, P and S by IC produces problems for analysts in that sample sizes are very small (typically < 0.2 g). Obtaining results from one such sample and relating its significance to what is usually a heterogeneous bulk waste such as a 40 000-L tanker is difficult.

10.2 Business Issues
The LHW industry segment has seen rapid growth, mainly for EDXRF instruments. The combination of both qualitative and quantitative analysis, capable of measurements within 30 min, is replacing the more traditional methods of AAS and ICPAES within the European and non-US market. Owing to the more “methods-regulated” and controlled industry within the USA this change has been slower.

10.3 Regulatory Issues
Specific methods, often prescribed for regulatory requirements, means that ICPAES, ICPMS and AAS, with their superior detection limits, will continue to dominate the ultratrace-level analysis of contaminants in drinking and natural waters. Although TXRF provides the same capability for most elements of interest, lack of internationally recognized methods limit its appeal.

LHW analysis is driven by performance-based methodology where ultralow detection limits are not required. Here, speed, accuracy of ±20% and low cost are the requirements of what is essentially a screening process.

11 FUTURE DEVELOPMENTS
11.1 Ultratrace Analysis Using Microsample X-ray Analysis
Microsample X-ray analysis (MXA™(26)) is a new technique developed initially for the silicon wafer fabrication industry where ultrapure acids and washing waters required rapid cheap analysis techniques. The MXA™ technique uses an ultrathin film, typically 0.15 μm thick, to support dried 5–50-μL samples for analysis. The sample is supported on a hydrophilic area in the center of the film. A sample is slowly dried over a 30–40-min interval and placed in an XRF instrument. The technique relies on there being very little scattered background radiation generated by the very thin support film. The X-ray beam is highly collimated to only excite the small (1–3-mm diameter) sample spot thus further reducing scattered X-ray background entering the detection system.

The limitation of this method is that to reduce scattered radiation or background introduction into the spectrum, very low total analyte concentrations are necessary. The general use of this method is therefore limited. However, as a method to analyze elements present in high-purity aqueous solutions, this technique has many advantages.

Element species not captured using other forms of trace analysis preconcentration may be detectable using the MXA™ technique applied to the supernatant liquid. Applying clean-up techniques to remove alkali metals and Ca, typically found in natural waters, such as those developed for TXRF, may allow this technique to become more widely applicable to environmental analysis.

This technique provides an alternative to the use of TXRF, currently used in the silicon wafer fabrication industry, with lower costs but poorer detection limits.

PORTABLE INSTRUMENTATION: INTRODUCTION

Portable Instrumentation: Introduction

Michel Goedert
Hewlett-Packard Laboratories, Palo Alto, USA

The section about Field-portable Instrumentation is a collection of papers about portable and transportable analytical instruments and chemical sensors available for analyzing gases and vapors in the field. We also would like it to be a reflection on field measurements and how to improve their quality. All the basic techniques described are mature and have well-established theoretical bases that can be found in other sections of the Encyclopedia. The reader will also find in this section several papers reviewing more advanced methods that are used for measurements of gases and vapors above and below the surface of the earth. In this way, we hope to present a more general approach to the complex problem of atmospheric air pollution. The description of optical analytical techniques is an important issue to field measurements and is treated in detail elsewhere in the Encyclopedia. We encourage the reader to check the other sections since these techniques are an important approach used for global measurements. A paper such as the one written by F. Rathgeb and G. Gauglitz about Optical Gas Sensors in Analytical Chemistry: Applications, Trends and General Comments, just to name one of them, provides useful information about the use of optical methods applied to field measurements.

The analysis of gas and vapors in the field is an important part of the remediation process. In the paper prepared by M. Goedert, Field-portable Instrumentation, the author gives a general review of field measurements using portable and transportable instruments. This review paper should give the reader an overview of the techniques available in the field. An important part of this article covers direct-reading instruments such as gas sensors, electrochemical devices, ionization detectors and colorimetric detectors. Portable instruments include miniaturized gas chromatographs and mass spectrometers and combinations of these techniques. The author also reviews a powerful, and lesser-known hyphenated technique that is a combination of gas chromatography (GC) and ion mobility spectrometry. It offers less resolution than mass spectrometry (MS) but operates at atmospheric pressure and is truly portable. In the past, ion mobility spectrometry has found applications in the battlefield to detect warfare agents. Civilian applications are presented in this paper. Chemical sensors are an important part of portable instruments used in the field and are treated in detail in this section. Sensors are generally required to be inexpensive, but must be reliable. In addition they should be user friendly and not require highly trained personnel to operate them. Chemical sensors are not as versatile as analytical instruments such as gas chromatographs or mass spectrometers, but they can usually provide a simple response to simple questions: Is this environment free of such or such toxic compounds? In their paper entitled Solid-state Sensors for Field Measurements of Gases and Vapors, F. Dickert and P. Lieberzeit review in detail the principle of operation and applications of several solid-state sensors. They show that chemical sensors are now solidly entrenched in the arsenal of tools available for field measurements, and can provide useful information about the environment for only a fraction of the cost of other analytical instruments.

Electrochemical sensors are an important part of the chemical sensor family. J. Cox and S. Holmstrom review them in their paper Electrochemical Sensors for Field Measurements of Gases and Vapors. These sensors are constructed using well-established engineering methods to produce small, compact devices with a high degree of robustness and reliability, freedom from orientation effects, intrinsically low cost and suitability for volume production. They are not very selective, but are sensitive enough to detect gases at the sub-ppm level and when used in array they provide a cost effective and powerful way to monitor combinations of gases in the environment.

An application of remote measurements using chemical sensors has been prepared by J. Hahn and addresses preliminary system engineering for a chemical-sensing network. The title of this paper is Chemical-sensing Networks: Satellite-based. It shows the potential of wireless measurements combined with sensors in the field. Sensors and earth-based receiver/transmitters would be linked to low-earth orbiting satellites and the chemical sensors periodically interrogated. The critical technical factors as to orbital analysis, telemetry, data rates, data structures, digital modulation techniques, antennae selection and so on are examined. More specifically the author describes: (1) design of the fiber optic network that will convey subterranean signals to and from the receiver/transmitters on the earth’s surface, (2) selection of long-lived, low-power sources for the remotes, (3) application of a pattern recognition algorithm to the frequency shift data that are conveyed to the central processing site’s computer at the satellite hub to facilitate the chemical identification of hazardous compounds, (4) satellite transponder access, and (5) the ability of the network to detect chemicals above and below ground.

More traditional chemical instrumentation than chemical sensors is available for field measurements and is

Encyclopedia of Analytical Chemistry

reviewed. In the article Field-based Analysis of Organic Vapors in Air, R. Berkley describes the results of several evaluations of portable gas chromatographs in the field organized by the US Environmental Protection Agency and other governmental agencies. He shows that field measurements are seldom accurate, mostly because the instruments do not operate well in nonstable environmental conditions. At the same time he emphasizes that analyses performed in a laboratory where the conditions are stable are also subject to important sources of errors due to potential sample degradation. The latter source of errors is difficult to estimate and certainly more difficult to correct than field instrumentation problems.

Is it possible to miniaturize analytical instruments even further? The answer is yes; the miniaturization of analytical instruments is now possible and has already been demonstrated. Portable gas chromatographs and mass spectrometers are becoming smaller and provide faster analysis than their laboratory counterparts. When a decrease in the versatility of the analysis is acceptable, the quality of data provided by portable units is comparable to the quality of measurements obtained with laboratory instruments. W. Higdon and M. Goedert have prepared a technical paper reviewing the subject of Microelectromechanical Systems Technology Applied to the Miniaturization of Field Instrumentation. Microfabrication uses the same tools and processes as microelectronics technology to prepare passive micro-electromechanical components for analytical instruments. Microelectromechanical systems (MEMS) applications to analytical chemistry instrumentation started in the 1980s at Stanford University with the design of a gas chromatograph on a chip for the NASA Mars Lender project and eventually led to the development of a commercial instrument.

In this section, the authors review techniques such as lithography, chemical and plasma etching, and evaporation of metal used to prepare MEMS parts. The advantages of this technology are the miniaturization of the parts and the analytical gain in performance that sometimes results from the reduction of the volume of the parts. For instance, fast GC analyses with small-bore columns would not be possible if the internal volume of the detector were not reduced. Analytical applications showing the gain resulting from MEMS are also reviewed in this paper.

The next category of measurement considered is mass dispersion methods. Progress in miniaturization of analytical laboratory instruments has made possible the development of portable mass spectrometers. G. Matz, W. Schröder and T. Kotiaho have prepared a review of the technology and applications in their paper entitled Mobile Mass Spectrometry used for On-site/In situ Environmental Measurements. MS, especially combined with gas chromatographic separation, is the most powerful, but also the most expensive and difficult-to-use, analytical tool available. MS is the only tool providing potentially a complete positive identification from the typical fragment patterns. It is fast (less than one second) and accurate (few percent or better). Its dynamic range is large (several decades) and sensitive (sub ppm).

Sample collection and injection in a gas chromatograph or a mass spectrometer is a difficult problem. An interesting solution, used for the isolation and preconcentration of organic samples from a variety of matrices, is described by L. Müller, T. Görécki and J. Pawlisyn in the paper Solid-phase Microextraction in Analysis of Pollutants in the Field. A microextraction is performed by a polymeric coating immobilized on a silica fiber and is based on partitioning of an analyte between the sample matrix and the fiber. The fiber is mounted in a device the size of a hypodermic syringe. Solid-phase microextraction (SPME) is applicable to solid, liquid and gaseous samples and integrates sampling with sample preparation. This attractive approach offers the advantage of solving several important analytical issues in a small package: separation of the sample of interest from the matrix, pre-concentration, and finally transportation and storage before analysis. The separation from the matrix can be done by immersion of the fiber in the sample or by headspace extraction above the sample. When sampling in the field using SPME there are two possibilities: (a) the sampling/sample preparation as well as quantification are performed in the field using SPME and a portable GC; (b) only sampling/sample preparation is performed in the field and the protected fiber with extracted components is then transferred to the laboratory for analysis.

One application paper presented here is about radon measurements. Radioactivity is the spontaneous transformation of the nucleus of an atom by the emission of corpuscular or electromagnetic radiation. Radioactive contaminants are also distinguished by the specialized and very sensitive methods available for the detection of radioactivity. Measurements of a few thousand atoms per liter are not uncommon. The various portable instruments used for measuring radon, thoron and daughter products are reviewed here by F. Cua in the paper entitled Radon, Indoor and Remote Measurement of.

When the source of contamination is underground, a different set of equipment is available to perform in situ measurements. One technology that is gaining widespread acceptance for rapid environmental site characterization involves the use of cone-penetrometer systems. This is another example of in situ on-line measurements of determination of water, soil and soil-gas from the subsurface. This technique is not “portable” but “transportable” and is described in the review paper
written by P. Doskey and E. Cespedes entitled Cone-penetrometer-deployed Samplers and Chemical Sensors. It requires a mix of heavy equipment to get under the surface and small, reliable and sensitive types of sensors and transfer lines to perform the in situ analysis. This paper describes the most recent progress made for on-line analytical and in situ chemical detection techniques into the cone penetrometer. Results from site characterizations are provided and compared with laboratory measurements.

What about global measurements? Pollutants are diffusing through the atmosphere and a three-dimensional representation of the problem is very often more useful than a punctual measurement. The paper Aircraft-based Flux Sampling Strategies prepared by R. Desjardins, J. MacPherson and P. Schuepp partially answers this question. It may represent a totally different category of transportable instrumentation, but indicates an approach that is worth mentioning about global measurements in the field. It describes the instrumentation used on flux aircraft, the type of data collected and their validity applied to environmental research. Gas exchanges are measured rapidly over large areas and provide a direct measurement of mass and energy exchange at the land/atmosphere interface. The amount of information that is potentially collectable from a specially equipped aircraft is considerable and is extremely useful for getting spatial information about ecosystems and possibly measurement of contaminated clouds. This paper reviews briefly the sensors used and discusses some of the problems associated with the sampling strategy. Positioning of the aircraft can be accurately measured with global positioning systems. The air temperature, carbon dioxide, vapor and ozone concentration can be determined with specific sensors. For trace analyses gas chromatographs have been used with success.

The use of mobile analytical instrumentation in the field offers numerous advantages over bringing the sample to the laboratory for analysis. Sample transportation is limited and consequently the sample degradation is minimized. Another advantage is that rapid identification is possible and suspicious results can be checked by immediate duplication of the analysis. Instruments used in the field should be ideally small and light, use a minimum of consumable fuel (electrical power and gases), operate for long periods without attention and be sensitive enough to detect reliably all contaminants. Unfortunately only a few of the field instruments available today meet these requirements. However, there are promising emerging technologies or analytical methods available today that have been developed for military and space exploration applications that may change the design of analytical instrumentation.

1 INTRODUCTION

Information on the magnitude and dynamics of the CO₂ and energy exchange of the Earth’s major ecosystems is essential if we are to predict the response of these ecosystems to global changes. Several large-scale projects have been carried out in recent years over a wide range of ecosystems such as grasslands, wetlands, mixed farmlands and forests, and boreal forests. Aircraft-based systems have been an important research tool during these experiments, for model evaluation, for the description of the spatial variability of surface fluxes, and for quantifying the effects of spatial variability on area-averaged surface fluxes.

The mobility of aircraft is a well-recognized asset to quantify fluxes for large areas over the entire depth of the mixed layer. This article reviews the current state of the art of aircraft-based flux systems. Although aircraft-based flux measurements are available from many research groups, as a matter of convenience, the examples used to illustrate the basic flux sampling strategies are taken from the authors’ research. This paper describes the instrumentation used on flux aircraft, the type of data collected and their quality control. It discusses the accuracy of aircraft flux measurements and presents aircraft–aircraft as well as aircraft–tower comparisons. Finally, flux measurements obtained over a wide range of ecosystems are presented as examples of the kind of information that can be obtained using aircraft-based systems.

2 TECHNIQUES OF FLUX MEASUREMENT

2.1 Eddy-covariance Technique

The eddy-covariance technique provides the most direct measurement of the gas and energy exchange at the land–atmosphere interface, without disturbing the...
environment under study. This technique integrates the flux, \( F_c \) over a mosaic of different sources and sinks. Based on Reynold’s approximation, it computes the mean products as

\[
F_c = \overline{\rho_a W C} = \overline{\rho_a (W' C_t + W \overline{C})} \approx \overline{\rho_a} \left( \frac{1}{N} \sum_{i=1}^{N} W'_i C'_i \right) \tag{1}
\]

where the mixing ratio of a scalar, \( C \), equals the sum of the mean mixing ratio, \( \overline{C} \), and the deviation from the mean, \( C'_i \). It is also equal to \( \rho_c/\rho_a \) where \( \rho_c \) is the density of the gas of interest and \( \rho_a \) is the density of dry air. Similarly, the vertical air velocity \( W \) is the sum of the mean vertical wind, \( W' \), and the fluctuation from the mean, \( W'_i \). All these values are measured at equal intervals of time over a certain time period. Reasonably stationary conditions, negligible horizontal advection and absence of chemical reaction involving the gas of interest within the air column below the measuring system, are required for accurate flux measurements. Ignoring these conditions, which may lead to flux divergence with height, may result in significant errors in surface flux estimates from aircraft-based systems.

The need for correcting the density of the gas of interest for temperature and water vapor fluctuations is now well recognized for flux measurements of gases using infrared (IR) gas analyzers. Depending on the configuration of the measuring system, the density correction will involve both, only one or none of the above. This correction, which is a function of \( \overline{C}/|F_c| \), results in an error of less than 10% for \( \overline{C}/|F_c| \leq 70 \text{s m}^{-1} \). It can either be done using the so-called Webb correction or by converting the density measurements to the mixing ratio of the gas of interest with respect to dry air. The latter is obtained by measuring the pressure, temperature and humidity of the air at the same time as the density of the gas.

### 2.2 Relaxed Eddy-accumulation Technique

The relaxed eddy-accumulation technique is a modification of the eddy-covariance technique, which has been developed for aircraft-based flux systems for gases for which no fast-response sensors are available. It involves the partitioning of the gas sample into two separate reservoirs, based on whether the real-time wind-measuring system senses ascending or descending air. The gas sampled can be analyzed later by a slow-response analyzer, such as a gas chromatograph. The conceptual simplicity of the technique is attractive, because the vertical flux estimate \( \overline{W C} \) for a trace gas is a simple function of the standard deviation of the vertical gust velocity \( \sigma_w \), the difference of the mean concentration of upward and downward moving gas samples, \( \overline{(C^+ - C^-)} \), and an empirical coefficient \( A \):

\[
\overline{W C} = A \sigma_w (\overline{C^+} - \overline{C^-}) \tag{2}
\]

Eddy accumulation systems have been flown on the National Research Council (NRC) Twin Otter and the Electra operated by the National Center for Atmospheric Research (NCAR).

### 3 INSTRUMENTATION

#### 3.1 Sensors

##### 3.1.1 Position

The versatility of an aircraft to act as a sensor platform is enormous (Figure 1). It is suitable to make flux measurements as low as 10 m and as high as the top of the mixed layer (1–2 km). Aircraft can also cover large horizontal areas. Various methods have been used over the years to record the aircraft position, from utilizing the aircraft’s basic very high-frequency omnirange/distance measuring equipment (VOR/DME), to Loran-C, to very low frequency (VLF)Omega, to Inertial Navigation Systems (INS), to the Global Positioning System (GPS). The INS and the current ring-laser gyro inertial reference systems (IRSS) are primarily used on flux aircraft for three-axis inertial velocity measurement, but their position outputs are also recorded, although these can drift by up to 2 km h\(^{-1}\) as a result of the Schuler oscillation.

The GPS represents the current standard for position measurement. When operated in the nondifferential mode, accuracy is limited to about 50 m because of “selected availability”, an intentional degradation of the GPS signals to restrict the full accuracy to authorized military users. However, centimeter accuracies can be achieved if the system is operated in the differential mode incorporating recorded signals from an accompanying ground station. In this mode, GPS also provides accurate measurement of the aircraft height above mean sea level. Flux aircraft carry radio altimeters and laser altimeters to measure the absolute height above the terrain. These measurements can be combined with pressure–altitude or GPS altitude data to produce records of the height and roughness of the terrain over which the flux measurements are being made.

##### 3.1.2 Air Motion

The most complex and demanding set of measurements from an aircraft is that used to calculate the three-axis wind components. Wind relative to the Earth is determined by the difference between two vectors: the
Figure 1  In major field programs examining the interaction between the atmosphere and the vegetated surface, both flux aircraft and flux towers are used, the aircraft providing spatial and the tower temporal coverage.

Airflow relative to the sensors and the motion of the sensors relative to the Earth. As the transit speed of the sensors is typically 10 times the wind speed, the two vectors nearly cancel, requiring very high accuracy in both for good wind resolution. For turbulence measurement, high-frequency response is required as well. The airflow vector is determined from the pressure distribution over a hemisphere pointed into the airstream. On some research aircraft, the hemisphere is the nose radome, sampled through five pressure ports. Many aircraft, including the Twin Otter in Figure 1, use smaller probes extended forward from the nose on booms. The Rosemount 858AJ probe has a hemisphere of 25 mm diameter with five pressure ports. The National Oceanic and Atmospheric Administration (NOAA) Long-EZ aircraft uses a 130 mm hemisphere employing nine pressure ports.

Two primary methods are currently used to measure the motion of the sensors relative to the Earth. Many aircraft utilize commercial INS/IRS, which determine their motion, heading, and attitude angles using high-precision accelerometers and ring-laser gyros. Position and velocity drifts, and resulting wind errors, are corrected during post-flight processing using Kalman filters or spline fits to positions given by GPS. Some aircraft rely entirely on GPS for low-frequency information, matching this with high-frequency data from relatively low-cost accelerometers and mechanical gyros. Commercial GPS systems are now capable of accurate direct measurement of an aircraft’s attitude and velocity in addition to position. After computing the vector difference between the instantaneous airflow and inertial velocities, most well-calibrated research aircraft should be able to measure the true wind component to an accuracy of 0.2–0.3 m s⁻¹ over a frequency range from 0 Hz to at least 10 Hz.

3.1.3 Scalar Sensors

Several fast response sensors are used to measure air temperature, CO₂, H₂O, and ozone concentration on flux aircraft. The placement of some of these sensors on the Twin Otter is shown in Figure 2. The measurements
are fed to an onboard data processor that applies the calibration constants for each sensor.

For air temperature, the sensor most frequently used is a Rosemount fast response heated (or unheated) probe mounted on the outside of the plane, typically on the nose. The probe has two time constants, 0.016 s for the thermistor and 1.15 s for the housing. Many operators use special high-frequency microbead thermistors installed in either Rosemount housings or in casings of their own design. Several sensors have been used to measure carbon dioxide and water vapor fluctuations. In the Twin Otter, an open-path IR gas analyzer developed by Agriculture and Agri-Food Canada had been used for about 13 years. It has a 100% response at 15 Hz, but is not suited to the measurement of absolute concentrations because of the drift in the absolute value. This instrument has recently been replaced by a new open-path IR gas analyzer that provides both the fluctuations and the average concentration with more accuracy. A slightly slower response LI-COR LI-6262 CO₂/H₂O analyzer is also used in the Twin Otter as a back-up unit. In other aircraft, LI-6262, Lyman alphas and other kinds of IR gas analyzers have also been used.

Several ozone analyzers have also been deployed on aircraft. A fast-response chemiluminescent sensor has frequently been mounted on the nose of the Twin Otter aircraft. A Scintrex LOZ-3 ozone detector, which detects the chemiluminescence produced when ozone encounters a surface wetted with a specially formulated solution of Eosin-Y, has also been tested. The data from this sensor, which has a time constant of the order of 1 s, needs to be corrected for high frequency attenuation for the flux measurements.

For trace gases for which fast-response sensors are not available, gas chromatographs have been used with success on air sampled with an eddy accumulation system to measure the fluxes of agrochemicals and volatile organic compounds (VOCs).

### 3.1.4 Radiation Sensors

The incident solar radiation can be measured with several kinds of pyranometers. It is important to continuously correct the radiometer readings for its mounting alignment and orientation changes due to variations in the heading, and the pitch and roll attitudes of the aircraft. Reflected solar radiation is also measured with a pyranometer. Surface temperature is measured using an IR radiometer. Net radiation (Rn) can be measured directly or it can be calculated from the net short- and long-wave contributions. The net short wave is the difference between incident and reflected solar radiation, and the net long wave is the difference between the downward and upward long-wave radiation. The downward long-wave radiation can be estimated from an empirical relationship based on air temperature. The upward long-wave radiation is estimated from the surface temperature measured using an IR thermometer and assuming an emissivity of 0.98. By taking the aircraft attitude angles into account, estimated Rn agreed within a few percent with Rn measured by the various tower-based systems.
during BOREAS (Boreal Ecosystem Atmospheric Study) 1994.\textsuperscript{(36)}

3.1.5 Spectrometers

Most flux aircraft now carry upward and downward looking spectrometers. The Skye Industries greenness indicator, which is based on the ratio of near-IR (730 nm) to red (660 nm) radiation, indicates the amount of green vegetation beneath the aircraft (Figure 2). The upward facing sensor allows for a possible normalization of the incident radiation to remove errors due to clouds. Another instrument used to measure vegetation characteristics is the downward looking Exotech 100BX satellite simulator. This simultaneously measures reflected radiation over four wavelength bands, and can be configured to simulate two modes of Landsat operation, i.e. thematic mapper (TM) and multispectral sensor (MSS), as well as the Système Pour l’Observation de la Terre (SPOT) satellite. Such sensors, when mounted on a low-flying flux aircraft, only provide information on a narrow strip directly under the aircraft, but these can be compared and integrated with wider scenes provided by various satellites. In most large-scale experiments many kinds of spectral data are collected. Wide-angle sensing spectrometers such as the ESTAR (electronically scanned thinned array radiometer) on the National Aeronautics and Space Administration (NASA) P-3 in the Southern Great Plains (SGP) 1997 Hydrology Experiment, measured surface characteristics that can be directly superimposed on the footprint sensed by the flux aircraft.\textsuperscript{(38)} This combination of data should result in much better correlations between flux measurements from aircraft and surface characteristics observed with airborne spectrometers.

3.2 Flux Measurements

3.2.1 Data Acquisition

Much progress has been achieved in the area of data acquisition. Improvements in computer speed, storage capacity, and ruggedness have made them much more reliable in the demanding environment of an aircraft, and have allowed the computation and display of an ever-increasing list of products, including real-time flux estimates. Signals to be recorded in flight originate in a host of analog and digital devices. In the Twin Otter, for example, the input/output (I/O) boards that interface to the input and output devices include RS232 serial boards, Arinc 429, DR11W, analog to digital, digital to analog, digital I/O, small computer systems interface (SCSI) and video graphics array (VGA) graphics. The analog signals are conditioned with a two-phase filtering process. First the signals pass through hardware and signal conditioning where each signal is low-pass filtered at 100 Hz, amplified and biased. These signals are then digitally sampled at a rate of 256 Hz. A digital 47-point 10-Hz low-pass filter is applied and the data are then recorded at 32 Hz on a 4 mm Digital Audio Tape (DAT). The 10 Hz low-pass filter implies that, at a true airspeed of 60 m s\(^{-1}\), the minimum resolvable wavelength is about 6 m.

3.2.2 Flux Calculations

Three sets of fluxes are normally computed for the flux calculation. These are computed from the raw, linearly detrended and high-pass filtered time series. The high-pass filtering routine uses a third-order algorithm with an adjustable breakpoint. If set at 0.005 Hz, at a flight speed of 55 m s\(^{-1}\) this corresponds to a wavelength of approximately 11 km. In using the eddy-covariance technique to compute fluxes, the data must be adjusted for the transport time for a parcel of air to pass from the noseboom, where the air velocity is measured, to the other sensors. This adjustment is particularly important for runs at low altitude, where the spacing of the sensors can become a significant fraction of the typical eddy size.\textsuperscript{(36)}

After comparing the cospectrum for vertical wind and water vapor using the LI-COR and the Agriculture Canada open path IR analyzer, a substantial underestimation at high frequency was observed by the LI-COR. By using a method to reduce high-frequency losses\textsuperscript{(26)} and assuming the LI-COR had a time constant of 0.2 s, both cospectra estimates matched very well.\textsuperscript{(34)} This correction is now also done for the H flux by assuming the 0.016 s and 1.15 s time constants for the temperature sensor and its housing.\textsuperscript{(34)} As expected, this correction is more important for low-level runs. A similar correction has been done with the vertical wind CO\(_2\) cospectrum. However, it has not been possible to validate this correction using the Agriculture Canada open-path CO\(_2\) analyzer because there is evidence that the CO\(_2\) fluctuations from open-path CO\(_2\) analyzers, which are about 10 times smaller than those of water vapor, are sometimes affected by aircraft motion.\textsuperscript{(39)}

3.2.3 Data Quality Control

In a typical field campaign, the aircraft-based flux system records about 100 parameters, 32 times per second for about 100 h. This represents about 1 billion measurements. Quality control of the data should be done during the data collection. This is best done by calculating the fluxes in real time and displaying them to the flight crew. Being able to observe the instantaneous flux measurements reduces the likelihood of collecting data with faulty sensors. A more comprehensive check on the quality of the data can be done after each flight by running the data through spike removal programs as well as examining
the spectra and co-spectra for anomalies.\(^{40}\) A procedure for controlling the quality of the data for both tower-based and aircraft-based flux systems has recently been described.\(^{41}\)

Errors can also result because the flux sampling criteria are not met due to a poor sample size, a result of either too short a run or an insufficient number of repeated passes.\(^{42}\) Nonstationary records are particularly troublesome. They should be omitted from the analysis because the calculation of the random and systematic errors are not valid and the computed fluxes are sensitive to the choice of averaging length.\(^{43}\) The practice of comparing the flux estimates from raw, linearly detrended and high-pass filtered time series can provide a useful screening for the presence of long-wave contributions to the flux estimates.\(^{44}\)

### 3.3 Other Aircraft-based Systems

There are many other research groups who are using aircraft-based flux systems. For example, airborne flux measurements of mass and energy were obtained over wetlands in Alaska from the NASA Electra platform.\(^{45}\) Four flux aircraft were operated during BOREAS-94: the University of Wyoming King Air, the NOAA Long-EZ, the NCAR Electra and the Canadian Twin Otter.\(^{46}\) The emphasis with all these aircraft was on spatial and temporal coverage. Durand et al. have studied the atmospheric boundary layer over complex terrain.\(^{47}\) The vertical structure of the marine atmospheric boundary layer has also been studied using two French research aircraft, a Fokker 27 and a Fairchild Merlin IV.\(^{48}\) Recently, the short- and long-term effects of clearing native vegetation for agricultural purposes have been studied in Australia using two research aircraft which belong to Flinders University.\(^{49}\) The Institute of Atmospheric Physics in Germany used three instrumented motorized gliders, flying in a coordinated stack, to make simultaneous measurements at three levels in the atmospheric boundary layer.\(^{50}\) There are many other groups who have either used or are using aircraft-based flux systems.

### 4 OBTAINING REPRESENTATIVE FLUX MEASUREMENTS

#### 4.1 Footprint Considerations

The flux footprint is the upwind surface area contributing to the flux density measured at a certain height. Determination of the flux footprint is particularly important for flux measurements from heterogeneous source distributions. Figure 3 compares the distances from which 80% of the flux contribution originates, when the fluxes are measured at 35 m above the vegetation, above a rough surface such as a forest and a smooth surface such as agricultural land. These curves are for unstable conditions; for stable conditions the area contributing to the flux is considerably larger. Such information is very important when one relates fluxes to surface features such as greenness indices and/or vegetation types. Following some of the earlier publications in footprint prediction of scalar flux,\(^{51},^{52}\) there has been much interest in this area of research.\(^{53}–^{55}\) For example, the footprint models over the boreal forest have been fine-tuned on the basis of controlled trace-gas release from the canopy.\(^{56}\)

#### 4.2 Flight Patterns

The choice of flight pattern (Figure 4) depends on measurement requirements and environmental conditions. Cross-wind profiling at several altitudes within the mixed layer, upwind and downwind of the area of interest, serves to quantify advection and flux divergence with height.\(^{12},^{13}\) Profiling and L-shaped patterns are also used to integrate fluxes over an area, and to extrapolate fluxes to the surface for terrain where low-level flights are not possible. Grid flights, which typically consist of about 8 legs of 16 km, spaced 2 km apart, are often flown at low levels. By repeating the whole grid pattern in the opposite direction, each pair of runs on each leg is flown at approximately the same average time, thereby minimizing temporal effects. This type of pattern helps to relate flux values to surface features.\(^{57}–^{60}\)

Straight transects are frequently flown past towers to evaluate the representativeness of tower-based measurements. Such runs are sometimes extended over long distances to quantify low-frequency contributions to flux and to compare regional flux elements with spectral data to develop spectrally based algorithms. In some cases, straight runs past a tower have been replaced by a circular pattern with a circumference of about 10 km, with comparable results.\(^{36}\)

Many other flight patterns have resulted in data that have not yet been fully explored. For example, a flight
AIRCRAFT-BASED FLUX SAMPLING STRATEGIES

leg over an interstate highway showed large negative fluctuations in ozone due to vehicular emissions of NO.\(^{61}\) Flights upwind and downwind of a large city have shown that the ozone concentrations downwind of the city were increased by up to 15 ppbv in the first 1500 m.\(^{62}\) Flights parallel to windbreaks have been used to understand their effects on energy exchange. Flights at night have confirmed that fluxes are close to zero at the top of the nocturnal boundary layer and flights near the top of the mixed layer under daytime conditions are helping to parameterize entrainment. Flights over a large lake in the boreal forest very early in the morning provided insight into the transport of carbon dioxide, water vapor, and ozone by local circulations at the time of transition from night-time to day-time boundary layer structure.\(^{63}\)

4.2.1 Aircraft–Aircraft Comparison

Comparisons between measurement systems in flight help to establish confidence in the accuracy of flux instruments, with long transects in close formation as the flight pattern of choice\(^ {64}\) (Figure 5). One advantage of this maneuver is that the aircraft analyze the same air parcels. An alternative to comparison between aircraft with different speeds, is the approximately coincident but independent grid sampling by both aircraft over the same region.\(^ {39}\) Figure 6 shows good agreement between the Wyoming King Air and the Twin Otter for H during BOREAS.\(^ {39}\) A consistent bias was observed between aircraft for the LE flux. During aircraft-to-aircraft comparison in SEMAPHORE (Structure des Echanges Mer–Atmosphère, Propriétés des Hétérogénéités Océaniques: Recherche Expérimentale) just the opposite was observed.\(^ {65}\) Better agreement between LE fluxes than H fluxes indicates that sensor
problems are probably the main cause of the disagreements. Many other aircraft intercomparisons were carried out during BOREAS\textsuperscript{46} and SGP-97.\textsuperscript{135}

4.2.2 Aircraft–Tower Comparison

Many comparisons have been made between tower-based and aircraft-based flux systems (Figure 7).\textsuperscript{36,66–69} Several factors complicate these comparisons. The aircraft run must be short enough to make sure that the aircraft flux footprint is comparable to the tower flux footprint, and yet the aircraft system must sample a sufficient number of transporting eddies to obtain a reliable flux estimate.\textsuperscript{42} Even if such a comparison is difficult to do, it is possible to demonstrate that both systems measure comparable fluxes.

Aircraft- and tower-based flux measurements obtained during the SGP experiment in 1997 are shown in Figure 8. The tower-based flux measurements were collected 1.5 m above grassland, and the airborne flux measurements 30 m above the surface along a 14.7-km track close to the tower. This is not an ideal situation for a comparison as the track was heterogeneous in terms of surface cover.\textsuperscript{34} Hence, to make the comparison more realistic, \( H \) fluxes were calculated for a 4-km segment close to the tower, as well as for the whole run. This segment consisted primarily of grasslands, similar to the vegetation near the tower. The aircraft-based fluxes are the average of 4–6 passes, whereas the tower data are averaged over 0.5 h periods during which the aircraft fluxes were being measured. For the segments close to the tower, the aircraft \( H \) flux was 0.97 of that of the tower \( H \) flux. The differences were not significant. For the whole run the \( H \) flux observed by the aircraft was 1.43 times the \( H \) flux measured by the tower.\textsuperscript{34} This is not surprising, considering that a large amount of the track was either dry bare soil or mature wheat.

Although no methods exist to provide absolute checks on the accuracy of flux measurements, the closure of the energy budget, i.e. the comparison of the sum of \( H \) and LE fluxes against \( R_n \) minus soil heat flux \( G \), lends considerable strength to eddy-covariance measurements. Figure 9 shows the sum of \( H \) and LE measured by the tower and the aircraft, versus \( R_n - G \) measured by the tower during the SGP project in 1997. The aircraft data is again limited to the segment near the tower. The aircraft \((H + LE)\) ratio is 0.86 of \((R_n - G)\), whereas the tower \((H + LE)\) is 0.80 \((R_n - G)\). An underestimation of 14–20\% of the \( H \) and LE fluxes has frequently been observed over agricultural land around midday when

![Figure 7](image-url) **Figure 7** Twin Otter aircraft during a flux run near a tower-based system over a wheat field in Manitoba, Canada.

![Figure 8](image-url) **Figure 8** Comparison of the segment and whole run \( H \) flux as measured by the Twin Otter at an altitude of 30 m versus a 1.5 m tower, during the SGP experiment in 1997.

![Figure 9](image-url) **Figure 9** Heat fluxes \((H + LE)\) measured by aircraft- and tower-based systems versus tower-based net \((R_n - G)\).
using the eddy-covariance technique.\(^{68,70}\) It probably represents the proportion of the exchange that takes place in forms other than turbulent flux and hence not measurable by the eddy-covariance technique. This percentage is lower over rough surfaces such as a forest.\(^{71}\)

5 APPLICATIONS

5.1 Ecosystem Characterization

5.1.1 Wetlands

Wetlands are important sinks of carbon. They cover an area of \(5–6 \times 10^5\) km\(^2\) worldwide, and consist of sedges, grasses, ericaceous shrubs, sphagnum mosses, and lichens. Carbon dioxide is assimilated by plants and stored in the peat layers, thereby providing a natural sink for atmospheric carbon dioxide. With the ever-increasing possibility of climate change, it is very important to understand the role and response of wetlands to climate change. Aircraft measurements collected around midday over a 25-day period suggested considerable environmental control on the magnitude of CO\(_2\) fluxes over wetlands.\(^{67}\) Figure 10 shows the CO\(_2\) fluxes measured at an altitude of 35 m over three regions near James Bay during the Northern Wetlands study. Even though these areas are completely different, the CO\(_2\) flux values are primarily a function of the air temperature. A high temperature results in relatively low CO\(_2\) absorption, and vice versa.

5.1.2 Boreal Forests

As part of BOREAS, flux towers were installed at relatively homogeneous locations for the major species in the boreal forest in order to make long-term CO\(_2\) flux measurements.\(^{72}\) To test whether tower-based fluxes could be scaled-up to obtain regional flux estimates, concurrent aircraft-based flux measurements were collected near these towers by flying a 16 x 16 km grid pattern at a height of approximately 35 m over the vegetation. Tower-based flux measurements and the relationship between aircraft- and tower-based measurements were used to estimate CO\(_2\) fluxes for the grid area on days for which grid average fluxes were available. Figure 11 demonstrates that even though the boreal forest is a very complex ecosystem, it appears possible to scale up tower-based CO\(_2\) fluxes collected over five of the major species to obtain a reasonably accurate area average of the fluxes.\(^{36}\)

5.1.3 Grasslands

Airborne measurements were used during FIFE (First International Satellite Land Surface Climatology Project Field Experiment) to quantify the spatial variations in CO\(_2\) and H\(_2\)O fluxes over a 15 x 15 km grassland area. The west side of the site was dry and warm whereas the most active vegetation was in the south-east (SE) quadrant. The July 28 footprint-adjusted H\(_2\)O fluxes, which are superimposed on the vegetation index picture obtained by the Soviet COSMOS satellite on August 9th, show that the evapotranspiration rate increases as the intensity of the red color increases, i.e. with the amount of green vegetation (Figure 12). The water vapor flux values are the average evapotranspiration of two passes over a 3.8 km segment.\(^{58}\) A water vapor flux of 100 W m\(^{-2}\) is equivalent to an evapotranspiration rate of about 0.15 mm h\(^{-1}\).

5.1.4 Agricultural Regions

Measurements of the CO\(_2\) and H\(_2\)O fluxes were made over mixed farmland in California at an altitude of 32 m (Figure 13).\(^{33}\) These values are 1-km averages with a 3-km running mean. Values of NDVI (normalized difference vegetation index) measured directly below

**Figure 10** CO\(_2\) fluxes over the Northern Wetlands near James Bay as a function of air temperature during the 1990 field campaign. The different symbols represent different transects covering at least 75 km.

**Figure 11** Measured and estimated CO\(_2\) flux for the grid flights during BOREAS in 1994, at the southern study area near Prince Albert, Saskatchewan.

**Figure 12** Mean CO\(_2\) flux and air temperature from July 28, 1994, during FIFE. The CO\(_2\) flux values are the average evapotranspiration of two passes over a 3.8 km segment. A water vapor flux of 100 W m\(^{-2}\) is equivalent to an evapotranspiration rate of about 0.15 mm h\(^{-1}\).
correlation also increases if one corrects for a horizontal offset between the flux values and NDVI because the run was flown into the wind. High correlation between maps of land use and energy exchange characteristics have also been shown in grid flights.\(^{57,60}\)

5.1.5 Urban Regions

Aircraft make it possible to obtain data over areas where towers would not be practical. Although difficult to arrange, aircraft flights over urban regions can provide valuable information on the amount of CO\(_2\) emitted from fossil fuel use or urban heat island or oasis effects. Figure 14 shows the 5-km mean CO\(_2\) flux measured along a 45-km section of a flight track that crossed the city of Fresno, California, during the afternoon of July 29, 1991,\(^{33}\) based on two passes flown at an altitude of 150 m. The track extended from about 15 km north-west (NW) of the city to approximately 15 km SE of the city. As expected, the rural areas are a sink for CO\(_2\) whereas the city is a source. The magnitude of the source appears to be relatively small because some of the CO\(_2\) emitted is absorbed by the trees in the city.

5.2 Development of Spectrally Based Algorithms

Extensive use of aircraft-based flux measurements will probably come from exploring their suitability as a ground truthing tool for a wide range of satellite-based estimates.\(^{73}\) Figures 12 and 13 clearly show that CO\(_2\)/H\(_2\)O fluxes, which are a measure of photosynthesis and transpiration by vegetation, are highly correlated with surface characteristics such as the amount of green vegetation (NDVI). Some refinements are required before these measurements can be directly used, such as removing the effects of other variables. In the case of Figure 15, for example, the solar radiation was decreasing during the latter part of the run. This resulted in smaller CO\(_2\) fluxes
AIRCRAFT-BASED FLUX SAMPLING STRATEGIES

Figure 15 CO₂ flux and the NDVI for a transect from Prince Albert, Saskatchewan, to Thompson, Manitoba.

over the last 200 km. The measurements demonstrate the potential of aircraft-based flux measurements for developing spectrally based algorithms for estimating CO₂ exchanges. The possibility of using other remote sensing measurements, such as radiative surface temperature and NDVI, to estimate the H flux over the boreal forest has also recently been demonstrated with moderate success.¹⁷⁴

5.3 Unmixing Flux Measurements

A technique for characterizing a wide range of species with fewer towers has been recently explored.¹⁷⁵,¹⁷⁶ This unmixing method superimposes the flux footprints for many sections of a grid on a land-cover map from a Landsat TM image to determine the fraction of each type of vegetation in the footprint area. This fraction of vegetation is converted into a fraction contributing to the CO₂ flux for each vegetation type, based on estimated contribution to the CO₂ flux for a wide range of species. A CO₂ flux value is then obtained by the least-squares technique for each of the species selected, and the values corrected by forcing the flux estimates to agree with tower data for the species for which tower data are available. Figure 16 shows the results for July 24 1994, from the BOREAS data set. It shows the mean CO₂ flux value obtained by the Twin Otter aircraft and the estimates at the time of the grid flight for eight vegetation types, i.e. wet conifer, dry conifer, mixed coniferous and deciduous, disturbed, fen, regeneration and visible burn. Case (a) is from a least-squares fit without any constraint; the other cases apply constraints forcing the estimated flux from the aircraft data to match the tower data for that species. The technique provides information for vegetation types for which no tower data are available.

6 SUMMARY

The interest in the use of aircraft-based flux measurements in environmental research has grown enormously since

Figure 16 Unmixed CO₂ flux for July 24, 1994, using (a) linear least-squares method, (b) conifer wet forcing, (c) deciduous forcing, and (d) conifer wet and deciduous forcing (CW = conifer wet, CD = conifer dry, Mi = mixed, De = deciduous, Di = disturbed, Fe = fen, Re = rejuvenated, VB = visible burn).
the late 1980s. An aircraft is the only means for obtaining flux average over a wide area. It combines the advantages of rapid deployment to points of interest with the ability to make measurements over large areas and a wide range of altitudes.

This report briefly describes the sensors used on aircraft-based flux systems. It discusses various sampling strategies for obtaining flux measurements over a variety of ecosystems. It also briefly discusses two promising approaches that remain to be fully explored – the development of spectrally based algorithms and the unmixing of fluxes from complex ecosystems.

Although no absolute check exists on the accuracy of aircraft-based flux measurements, comparison with tower-based measurements shows that over grasslands both systems give comparable results. Based on energy budget considerations, however, the fluxes from both systems appear underestimated by about 15–20%. This underestimation, which has frequently been reported with the eddy-covariance technique, appears to be largest for smooth surfaces under high radiation and low wind conditions.

The examples presented should document the potential use and value of aircraft-based flux measurements. Much remains to be further explored, particularly in the area of ground truthing for the wide range of remote sensing observations. It is also important to develop sampling strategies that can provide estimates of diurnal cycles of fluxes.

ACKNOWLEDGMENTS

The assistance of the many scientists and technicians who contributed to data collection and analysis is gratefully acknowledged. The financial support of the following agencies during the collection of the aircraft data is also gratefully acknowledged. These are NRC of Canada, NASA, Agriculture and Agri-Food Canada, Atmospheric Environment Service of Canada, California Air Resources Board, National Science and Engineering Research Council and Canadian Institute for Research in Atmospheric Chemistry.

AIRCRAFT-BASED FLUX SAMPLING STRATEGIES

This paper addresses preliminary system engineering for a disposable, remote, chemical-sensing network. This network could interconnect a satellite hub, low-earth orbiting (LEO) satellites, remote sensors, and a fiber optic (OF) interface that interlinks remote chemical sensors, situated underground in aquifers or directly beneath hazardous chemical/waste sites, with remote transmitter/receivers on the earth’s surface. Some critical technical factors: orbital analysis, telemetry, data rates, data structures, digital modulation techniques, antennae selection, remote power considerations, satellite transponder access, and other hardware tradeoffs, are examined in an effort qualitatively to optimize the configuration of a wide area network (WAN). This paper demonstrates the viability of the proposed network, which is suited to the detection of hazardous chemicals in the atmosphere or underground.

1 INTRODUCTION

In this article, a new approach to chemical-sensing networks is addressed. This conceptual design will implement surface acoustic wave (SAW) sensors, in association with sensor arrays, fiber-optic links, earth-based receiver/transmitters, and LEO satellites – all working in tandem within a WAN. All major subsystems and technical considerations of this remote chemical-sensing network and their attendant preliminary system engineering will be discussed. The first of these considerations is: how does one most effectively sense the presence of chemical agents or hazardous chemicals in a local area and communicate their presence with adequate notice to appropriate authorities and/or participants, thereby permitting them to take the necessary precautions? The current consensus appears to be that there are three generally accepted chemical sensor techniques: electrochemical sensing, ion mobility spectroscopy (IMS), and SAW chemical sensing.

In the electrochemical sensing method chemical vapors are ionized via a radioactive source. These ionized vapors then pass through an electromagnetic field, where different chemicals are distinguished according to their differences in charge and resulting characteristic residence times in the electromagnetic field.

IMS distinguishes between chemicals via differences in charge and mass of ionized vapors in their flight paths.

SAW sensors distinguish between chemicals via shifts in the resonance frequencies. Each sensor has a cylindrical shape, and is impregnated on its periphery with a polymer coating, which is a radio frequency (RF) transmission medium. Currently there exist approximately eight polymer coatings. When each unexposed coating has an RF signal propagate along its length, it demonstrates a characteristic resonance frequency. However, when a foreign substance contacts the polymer coating, the resonance frequency will change – the magnitude of frequency shift depending upon the amount of foreign chemical coming in contact with the coating and the identity of that chemical. An empirically determined database must be called upon to properly evaluate the chemical patterns resulting from the presence of each foreign chemical on a SAW sensor. The pattern-recognition algorithm that is used to identify the foreign chemicals considers, among other things, the polymer coating types employed in each SAW sensor array and the degree of frequency shift that has been observed. The pattern recognition algorithm will then correlate the polymer coating types...
with the degree of resulting resonance frequency shift for each foreign chemical at a particular sensor array, using primarily this information to compare to a chemical database at the satellite WAN central processing site. It is then at this central processing site, that the foreign chemical is identified. The central processing site for such a LEO WAN is typically located at the satellite network’s ground station, alternatively referred to as the ground segment. The LEO satellites of this network may do routine computations, but the ground station serves as the control center for the entire chemical-sensing network. The respective satellites relay information to the central processing site at the ground station, but all important mission operations are orchestrated through the ground station.

If the presence of potentially hazardous foreign chemicals has been sensed, how can this information be most effectively disseminated to the appropriate interested parties? Three common communication options would be:

(1) transmission of chemical information from remote chemical sensors to a land-based transponder via a terrestrial communication link;
(2) transmission of chemical information from remote chemical sensors to an airborne transponder; and
(3) transmission of chemical information from remote chemical sensors on the surface of the earth to LEO satellite(s).

Qualitatively speaking, option (1) appears to be the least attractive. Large side lobes of remote antenna patterns would enhance the probability of detection and compromise in hostile, or business confidential, environments, and the prospect of “drop outs” on the communication link would be significant because of line-of-sight obstructions between remote sensors and the earth-based transponder – especially so in the case of a mobile, earth-based transponder, where obstructions to the signal path will be regularly encountered as the transponder moves.

Obstructions to the line-of-sight and fading due to the multipath effects should render this option the least viable of the three. On the other hand, the airborne transponder of option (2) would be less susceptible to line-of-sight obstruction and multipath fading, since the communication links would not be propagating as near to the earth as in option (1). Finally, option (3) would appear to be the most versatile, as it affords the least prospect of line-of-sight obstruction and multipath fading – owing to its more vertically directed communication links. Although in peacetime an airborne transponder would be quite appropriate, an aircraft flying in a periodic fashion overhead would evoke suspicion in the minds of hostile observers. A LEO satellite is harder to detect, thereby providing more confidentiality to its users, and also providing no prospect for endangerment to human life. It is appropriate to mention at this point that, although the types of satellite-based, remote-sensing techniques henceforward advocated for commercial and/or confidential applications in this article might be enhanced to the point of rendering them militarily secure, addressing such enhancements was not the objective of this author and, as a result, is beyond the intended scope of this article. The major points to be offered here will address a satellite-based WAN for, at most, confidential business applications.

As the third option is the most practical of the three, the remainder of this article will focus on remote-sensing configurations of the LEO satellite variety. In order to ensure success of the LEO satellite option, as a minimum the following preliminary system engineering considerations must be addressed:

(1) execution of an orbital analysis to determine the number of satellites, the orbital characteristics of each satellite, velocity, orbital period, stabilization error, etc., the desired availability of the satellites to the remote sensors, and the maximum antenna coverage attainable per satellite;
(2) determination of both the associated bandwidth allocations for transmit and receive data and frequency plans for transmit and receive channels that ensure levels of cochannel and adjacent channel interference at or below the thermal noise floor;
(3) selection of antenna types for both the satellites and remote sensors in accordance with design objectives;
(4) definition of the data structure and its associated telemetry format;
(5) determination of the optimal method of accessing the LEO satellite transponders, providing the maximum of performance and security that is consistent with cost constraints of a disposable, economical, remote chemical-sensing network;
(6) selection of modulation techniques that are amenable to low-cost, low-power remote sensors, i.e. selection of spectrally efficient modulation techniques for power-limited transmission from remote to transponder and noncoherent detection of signals at remote sensors which have been transmitted from the LEO transponder;
(7) selection of an economical power source that provides sufficient power for the remote chemical sensors; and
(8) verification of feasible and acceptable performance of communication links in this proposed remote...
chemical sensor network via computed figures of merit, resulting from a link budget analysis.

2 ORBITAL ANALYSIS

For the sake of convenience a polar, circular orbit of 250 km will be arbitrarily chosen. Since the circular orbit is a special subset of elliptical orbit types, Kepler’s Laws(5,6) for the period of satellite revolution and velocity of elliptical orbit are used, yielding an orbital velocity of 7.755 km s\(^{-1}\), or 17 340.4 mph. Similarly, the period of revolution is 1.4917 h, 89.50 min. Using the fact that the maximum possible antenna coverage from an altitude of 250 km is at that antenna beamwidth which provides a solid angle that is tangent to the earth’s circumference at right angles to the earth’s radius, yields a maximum antenna beamwidth of 148.4 degrees. In addition, we will specify that the satellite be 3-axis stabilized with a stabilization error of \(\pm 5\) degrees, for the sake of convenience (although at this writing the stabilization error can be less than \(\pm 1\) degree(7)). Then, in order to account for the stabilization error uncertainty, 10 degrees must be added to the computed antenna beamwidth - for a total required beamwidth of 158.4 degrees. This result indicates that satellite transmit and receive antenna patterns should approach hemispheric antenna patterns if they are to achieve the maximum antenna coverage. An antenna beamwidth of 148.4 degrees subtends an arc of 31.57 degrees on the surface of the earth, referenced to the earth’s center. Unfortunately, although this design configuration would afford the maximum realizable antenna beamwidth, we compute from the orbital geometry that it would require 11.4 LEO satellites at an orbital altitude of 250 km, which must naturally be rounded to 12 LEO satellites orbiting at 250 km altitude. This implies that the revised, narrower antenna beamwidth subtends an arc of 30.0 degrees on the surface of the earth, referenced to the earth’s center. This arc is a radial section of the earth’s surface, that is 3339.51 km across. For an orbit of 250 km altitude, the orbital velocity is 7.4625 km s\(^{-1}\), which corresponds to a linear velocity on the earth’s surface of 7.4625 km s\(^{-1}\). This says that a LEO satellite is made available to each of the 12 antenna coverage zones on the earth for a duration of 447.5 s, or 7.458 min. That is, in order for each of the 100 remote sensors (or remote sensor arrays, in the case of the SAW sensor arrays) to be polled for chemical information while the LEO satellite is overhead in their coverage zone, all chemical information must be transmitted during the 447.5 s when that LEO satellite is available to the coverage zone. If a 1% duty cycle is used for each transmitting sensor, or sensor array, then the total time of transmission for all 100 sensors reduces to 4.475 s, and the time of transmission for each of the 100 sensors is reduced to 0.044 s.

Therefore, if 100% satellite availability is desired in this application, i.e. a LEO satellite must be within communication range of the chemical sensor network at all times, a minimum of 11.4 satellites would be needed to achieve maximum antenna coverage – according to application of orbital geometry, where the slant range is a maximum of 1803.2 km at the maximum beamwidth of 148.4 degrees, and the slant ranges at distal edges of the beamwidth are tangent to the surface of the earth. Each of the antenna beamwidths for these 11.4 satellites would subtend a corresponding arc of 31.57 degrees, relative to the center of the earth, translating to an arc that spans 3514.27 km across the surface of the earth. This naturally would be rounded to 12 satellites. When 12 satellites are implemented, the antenna beamwidth narrows to 141.02 degrees, subtending an arc of 30 degrees relative to the earth’s center, which corresponds to an arc that is 3339.51 km across.

This orbital geometry can be more easily explained if the reader now refers to Figure 1, which depicts an orbital diagram and some orbital parameters for such a mission. In Figure 1, angle ASD represents the required antenna beamwidth for the LEO satellite antenna. This antenna pattern should approach hemispheric in type. In keeping with the knowledge that 11.4 LEO satellites would ensure that angles SAC and SDC are at right angles to the earth radii at points A and D, and the slant range

Figure 1 Some orbital characteristics for the proposed chemical-sensing network LEO satellite, \(\angle ACD = 30 \text{ deg} = 2 \angle ACS\); \(\angle ASD = 141.0 \text{ deg} = 2 \angle ASC\) = required antenna beamwidth; \(\angle SAC = \angle SDC = 94.5 \text{ deg}\); \(h = \text{altitude} = 250 \text{ km}\); \(z = h + r = 6378 + 250 = 6628 \text{ km}\); \(y = \text{slant range} = 1715.62 \text{ km}\); time of transmission = 0.04475 s; 12 LEO satellites at 250 km; 12 LEO satellite coverage zones each span 3339.51 km arcs on the earth’s surface; time to traverse LEO coverage zone = 447.51 s; overhead bit set + chemical sensor data set: (a) for electrochemical sensor, 18 bits; (b) for IMS sensor, 32 bits; (c) for SAW sensor, 116 bits.
would be 1803.2 km, a more realizable 12 satellites should yield a slightly narrower required antenna beamwidth of 141.0 degrees. This compares to the required antenna beamwidth in the former case of 148.4 degrees. For the 11.4 satellite scenario recall that the arc of the earth spanned by the LEO satellite’s antenna coverage zone was 31.57 degrees, relative to the earth’s center. Then a slightly narrower antenna beamwidth would reasonably span 30 degrees. Similarly, the narrower beamwidth and coverage zone in the 12-satellite case would necessitate a slightly higher angle at points A and D than 90 degrees (94.5 degrees). Figure 1 depicts the required antenna beamwidth. but also the longest side, SC, of the two symmetric triangles. These two triangles coincide roughly to the LEO antenna pattern’s beamwidth, which is 141.0 degrees in the 12-satellite case. The half angles of these two triangles, angles ASC and DSC, are 70.5 degrees each. This common side has a length equal to the earth radius, plus the satellite altitude of 250 km. The second angle of each triangle is 1/2 the angle subtended by the beamwidth (referenced to the center of the earth), or 15.0 degrees. The third angle of the triangle is the sum of the first two angles subtracted from 180 degrees, or 94.5 degrees. Using the law of cosines, the slant range comes to 1715.62 km. With the slant range now known, the elevation angle is computed, having a value of 1.00 degrees.

To recapitulate on the dynamics of data transmission to the available LEO satellite, it is available to the antenna coverage zone for 447.5 s. For this 1% duty cycle application, all 100 sensors will transmit their data to the LEO over a total period of 4475 s. Each sensor is randomly allotted a 4.475-s time slot, in which to transmit its overhead bits and chemical data sensor set. Chaotic circuits at the ground station would then randomly select a 0.04475-s interval within this 4.475-s time slot for transmission of data to the available LEO overhead. This fact implies that 99% of any remote’s allotted time slot with the overhead LEO satellite is unused, but if a chemical emergency ensues at another chemical remote, not next in the polling sequence but somewhere else in the same LEO’s coverage zone, the polling sequence will be adapted to accommodate such emergencies. Prospective methods as to how such chemical emergencies might be addressed effectively by the chemical-sensing network are elaborated upon further in sections 5 and 6. At this point, it is best to say briefly that an emergency transmission will be permitted soon after the currently transmitting sensor has finished its transmission.

In order to mitigate the possibility of remote collisions, i.e., two remotes sending communications to the proximal LEO transponder at the same time, it is recommended that an inactive period be established immediately after the conclusion of each sensor transmission. For example, since the time of transit for any sensor transmission would require a worst case 0.0057 s to contact the LEO overhead, a 0.3 s inactive time window after each sensor transmission is allotted (before the polling sequence is resumed). This 0.3 s of idle time is not expected to compromise the effective operation of the network. On the other hand, contaminated sensors should have higher prospects of communicating their emergency status to the available LEO, without costly time delays. The only apparent consequences of this modification would appear to be a moratorium of 30 s duration on polling requests to be relayed by the available LEO satellite, during its 447.5-s period when it is overhead in one of the 12 satellite coverage zones, and a reduction in delay times prior to communication with the available LEO satellite – regarding chemical emergencies that may exist in the vicinity of the notifying sensor.

Only the chemical sensors that have been exposed to chemical emergencies would be empowered to communicate with the LEO satellite at a time not dictated by the polling sequence. Such sensors would be required to have a pre-empt bit value of “1”, in order to send chemical data to the available LEO satellite on an out-of-turn basis. (See sections 5 and 6 for more elaboration on data structures and telemetry formats, and LEO transponder access.) Those sensors which have been exposed to hazardous chemicals would simply enter a queue of remotes needing to transmit hazardous chemical information to the nearest LEO transponder. In the event that there are no other sensors in queue with hazardous chemical data to transmit, that remote would wait to be polled by the LEO transponder during that transponder’s next inactive period. (This presumes that the ground segment has the capability to adapt its polling sequence as per a remote’s chemical environment, and that demand assignment multiple access (DAMA) is chosen as the transponder access method.) In the unlikely event of widespread chemical contamination, to the extent that sensors are unable to communicate with the available LEO for prolonged periods, their data may be buffered at the sensors for later transmission to the next LEO satellite to pass over that coverage zone.

3 A FREQUENCY PLAN CONFIGURATION THAT ENSURES LOW LEVELS OF CHANNEL INTERFERENCE

This frequency plan was chosen because, after appropriate interference analysis and consultation of National
CHEMICAL-SENSING NETWORKS: SATELLITE-BASED

Figure 2 Fundamental satellite links for this WAN. Note that each remote SAW sensor array is either attached on the earth’s surface to its nearest receiver/transmitter, or connected to it from underneath the earth’s surface via an OF link.

Telecommunications and Information Administration (NTIA) Tables, it was demonstrated that all potential adjacent channel and cochannel interference resides at or below the thermal noise floor for this specific frequency plan. As depicted in Figure 2, the polling link from the ground station, i.e., ground segment, to the LEO satellite is transmitted at a frequency of 2685 MHz, and modulated in a noncoherent, frequency-shift keyed (FSK) manner. The polling link originates at the ground segment, from which a noncoherent FSK digitally modulated signal is transmitted at the modulated carrier frequency of 2685 MHz to the LEO satellite. At the LEO satellite the noncoherent FSK signal is then downconverted to 400.13 MHz, and transmitted to the remote chemical sensors, either near or on the earth’s surface. The implementation of noncoherent FSK on the polling link enables the use of an economical, simple envelope detector as the remote’s receiver.

On the return link, from remote, to LEO satellite, to ground segment, the remote chemical sensor initiates transmission of a modulated carrier frequency of 469 MHz. A spectrally efficient digital modulation technique is best suited to this power-limited transmission on the return link from the diminutive remote to the LEO, where coherent binary phase-shift keying (BPSK) is recommended for this return link service. At the LEO satellite the return link signal is then upconverted to 2650 MHz, before it is directed back to the ground segment.

4 SELECTION OF ANTENNAE

In this section the antenna types for both the LEO satellites and each of the remote sensors need to be chosen. In the case of the LEO satellite, an antenna pattern approaching hemispheric provides the satellite its broadest possible access to chemical sensors positioned on the earth’s surface – within a coverage disk that is 3339.51 km in diameter. On the other hand, the remote sensors may be equipped with antennae that exhibit more directive antenna patterns, so that the remote antenna beamwidth and its associated solid angle is narrower, thereby resulting in less loss of power and a higher quality of signal reception at the satellite receiver in the face of power-limited transmissions from the chemical remote sensors. However, if 100% satellite availability is desired, a more directive LEO satellite antenna pattern would also necessitate more satellites. For example, if the new satellite antenna pattern were one fourth the beamwidth of the currently considered antenna, or 35.25 degrees, four times more satellites, i.e., 48, would be required instead of 12. The cost for a disposable, economical, LEO satellite network for these additional 36 LEO satellite deployments would be prohibitive. Nevertheless, sample computations indicate that the link margin could be as much as 10.8 dB higher with a transmit antenna that transmits at one fourth the beamwidth of the nearly hemispheric antenna pattern (141.0 degrees).

Since the link margin in the worst case, from hub to available LEO satellite, to the remote sensor on the polling link, is 4.89 dB at 10E(-6) bit error rate (BER) in the satellite WAN’s current satellite configuration, it would appear that a more directive LEO antenna pattern is not absolutely necessary for this application. Prospective LEO satellite antennae for this economical, remote-sensing application must exhibit simplicity of design, insignificant ground planes, compact size, diminutive weight, circular polarization, and an approximately hemispheric antenna pattern. Such an antenna is a quadri-filar helix antenna, according to Johnson and Jasik.

Further, circular polarization is, in general, a desired trait where communication via satellites is concerned. Conversely, as mentioned previously, a more directive remote antenna pattern will result in both a clearer reception at the satellite transponder and a more powerful transmission of the remote’s transmitted signal, which is especially attractive in a scenario such as this, where the remote sensor’s transmission is power-limited. An axial mode antenna is the antenna of choice for the remote’s power-limited service. This axial mode antenna would be used to both receive and transmit signals from the remote. It has
no ground plane, is compact and lightweight – while offering a fairly directive antenna pattern, whose maximum gain is realized along the helical axis.\(^\text{10}\)

5 DATA STRUCTURE AND ASSOCIATED TELEMETRY FORMAT

Three data structures will be addressed here, one for each of three chemical sensor options. In the case of the electrochemical sensor, four bits are needed for each sensor data set. This includes two bits to indicate whether the threshold for any of four nerve agents, or similarly behaving neural irritants, have been exceeded. Similarly, the other two bits will indicate whether the safety threshold for any of the four most common blister agents, or similarly behaving skin irritants, have been exceeded, in addition to the 14 overhead bits, for a sum total of 18 bits.

IMS is the second of the chemical sensor techniques that is commonly used to assess the presence of foreign chemicals in the environment, and requires eighteen bits for its sensor data set. Nine bits are allocated for nerve agents, or similarly behaving irritants, and the other nine bits for blister agents, or similarly behaving skin irritants. The nine bits pertaining to chemicals affecting nerves will give some indication as to the identity of the nerve agents or irritants, in addition to informing as to the severity of the exposure – thereby implying what protective action should be taken by humans in the immediate vicinity of these dangerous chemicals. The nine bits that are allocated for the blister agents, or similarly behaving skin irritants, are utilized in an analogous manner as those for nerve agents, with the same 14 additional overhead bits used as aforementioned with the electrochemical sensor.

A 4-SAW sensor array requires 60 bits for its sensor data set, 15 for each SAW sensor. For each of the SAW chemical sensors, the fifteen bits communicate in a binary format the magnitude of frequency shifts that result when a sensor’s polymer coating becomes impregnated with a foreign chemical. These 15 bits would then allow binary codes to quantify frequency shifts of up to \(2^{15}\), or 32768 Hz. These bits are again in addition to 14 overhead bits allocated for each of four SAW sensors in the array, for a total of 116 bits \((4 \times 15) + (4 \times 14)\). For each of the three chemical sensors enumerated in the prior paragraph, overhead bits are allocated, in addition to those included in the sensor data sets. There are 14 overhead bits which add to the data sensor sets for both the electrochemical sensor and the ion mobility spectroscope, and 14 overhead bits that add to the sensor data sets for each of four chemical sensors in the 4-SAW array. This comes to a total of 18 bits (overhead bits and data sensor set combined) for the electrochemical sensor, 32 bits (18 in the IMS sensor data set, plus 14 overhead bits) for the ion mobility spectroscope, and 116 bits for the 4-SAW array (15 frequency shift bits for each SAW sensor, plus 14 overhead bits for each SAW sensor). The foregoing data structures for each of three sensor types will have 0.04475 seconds to transmit (see section 2), implying that the data rates for the electrochemical sensor, ion mobility spectroscope, and SAW sensor array are 402 bps, 715 bps, and 2592 bps respectively. Overhead and total bit allocations are as follows:

1. Electrochemical sensor total bits (14 total overhead bits and 18 total bits):
   a. one start and one stop bit (two total bits),
   b. a numerical identifier, designating each of the 100 remote sensors in the remote chemical-sensing network with a unique numeric value (seven total bits),
   c. as no polymer coating will be applied to the electrochemical sensor, four bits will occupy overhead bit positions 10 through 13, where bits 1001 indicate this sensor,
   d. a pre-empt bit “1”, to alert that a sensor has detected hazardous chemicals, to pre-empt a sensor in the polling sequence, that is not in chemical contact currently with a hazardous chemical (one bit),
   e. additional to overhead bits, below/above threshold for poisons hazardous to human nervous systems (two bits),
   f. additional to overhead bits, below/above threshold for hazardous chemicals that cause blistering of human tissue (two bits);

2. IMS overhead bits with same breakdown as for the electrochemical sensor’s overhead bits (with same fourteen overhead bits and bits 1010 to indicate the IMS sensor), 14 overhead bits and 32 total bits:
   a. nine bits for chemicals hazardous to human nervous systems, indicating levels of concentration and probable chemical identity, and
   b. nine bits for chemicals causing blisters to human tissue, indicating levels of concentration and probable chemical identity;

3. 14 overhead bits for each of the four SAW sensors in a 4-SAW array (56 total overhead bits and 116 total bits):
   a. one start and one stop bit (two bits),
6 DETERMINATION OF THE MOST PRACTICAL TRANSPONDER ACCESS TECHNIQUE FOR THIS APPLICATION

Three prospective modes of satellite transponder access will be evaluated qualitatively:

(1) random access,
(2) code division multiple access (CDMA), and
(3) adaptive polling with random burst transmissions from the remote chemical sensors to the LEO satellite transponder – a variant of DAMA.

On the basis of fundamental cost/benefit analyses, all three transponder access techniques were evaluated as to their relative merits.

6.1 Random Access

Option (1) was analyzed first, and its merits will now be assessed. In a disposable, economical remote chemical-sensing network, this option has several disadvantages, in both commercial and military senses. From the standpoint of bandwidth requirements, in order to ensure that the incidence of simultaneous transponder “collisions” by two or more sensor-transmitted signals is 10% or less, the bandwidth requirements are generally as much as twenty times the information bandwidth. Here the information bandwidth would be conservatively twice the data rate. “Collision” in this sense refers to two or more transmitted signals arriving at a satellite transponder at the same time and frequency. This necessary increase in bandwidth for a random-access transponder application also would require proportionately greater power at the satellite, adversely affecting its compact size and low cost. Additionally each random-access remote sensor will continue to transmit to the LEO satellite overhead at random intervals, when the satellite is within range. Such a quality is not an asset in a military application.

In summarizing, the random-access technique may be acceptable for some commercial services, but its excessive power requirements and frequent transmissions render it undesirable for services where confidential transmission, low prospect of detection, or economy of cost and size are principal considerations.

6.2 Code Division Multiple Access

In Option (2), the feasibility of using CDMA for this application will now be addressed. To initiate this performance comparison, the author consulted two manufacturers of spread spectrum multiple access (SSMA) transmit and receive equipment. Each of these manufacturers stated that direct sequence (DS) spread spectrum would be more expensive than frequency hopped spread spectrum (FHSS), whereas the random burst transmit/receive technique would be cheaper to implement than either of the spread spectrum methods. Additional research in popular technical references served to corroborate these engineering consultancies. The frequency hopping approach calls for a frequency synthesizer that is adept at switching carrier frequencies very quickly, which serves as a complicating factor for its hardware design. However, noncoherent detection that can be realized with simple envelope detectors is sufficient to perform the receiver function for frequency hopped (FH) CDMA. Before the received signal can be demodulated at the envelope detector, its receiver must acquire and track the pseudorandom noise (PN) code that has defined the sequence of hopping during the signal’s transmission – and finally dehop the FH signal to its baseband frequency. The FH CDMA method, although using more bandwidth over time than a non-SSMA technique, will, for an instant at each frequency hop slot, occupy the same information bandwidth as would one 116-bit word of a non-FH SAW sensor word of chemical data – where each “slot” is about the width of the information bandwidth necessary to modulate a sensor’s data emission (overhead bits plus its sensor data set). That is to say, at any instant, the modulated FH CDMA signal’s bandwidth is typically similar in magnitude to non-CDMA transmission at the same frequency. On the other hand, a DS CDMA signal must be allocated much more bandwidth continuously than its FH counterpart; it therefore requires commensurately more power than does FH CDMA. Similarly, a high hopping speed of the carrier frequency is essential to the FHSS method, but not at all for the direct sequence spread spectrum (DSSS) method. In a similar fashion to its FH counterpart, the PN code for DSSS must first be acquired, tracked, and despread before the demodulation process can begin at the receiver. The demodulation process at the DS receiver typically entails...
coherent demodulation of a phase-shift keyed (PSK) digital signal. In summarizing the CDMA method, it would appear that the greater power requirement of DS (with its associated higher bandwidth requirement), and its more complex detection apparatus, make it more expensive to implement. The high-speed frequency synthesizer adds some additional expense to the FH method also, exceeding the cost of a typical receive/transmit approach without spread spectrum. Finally, in order to render a CDMA communication system more “confidential” or “secure”, it should be made resistant to jamming, difficult to intercept, and difficult to detect. However, owing in part to the additional cost for hardware to perform PN code acquisition and tracking and signal encryption, spread spectrum communication systems are appreciably more expensive than their non-CDMA counterparts.

6.3 Adaptive Polling with Random Burst Transmissions

The adaptive polling system with burst transmissions, as would be generated by proposed chaotic circuits for this communication system, is simply a variant of DAMA and, as such, is more economical, more simply designed, and smaller in size and weight than would be either Option (1) (Random Access) or Option (2) CDMA, which would exhibit higher costs and weights than Option (3).

The general application of adaptive polling with random bursts of data, whose random transmissions are induced via chaotic circuits[11,12,14–16] is conceived to operate as follows. Each of the one hundred remote chemical sensors envisioned in the LEO satellite’s antenna coverage area, will be designated with a permanent numerical identifier. Each sensor’s order in the polling sequence is determined via random selection of its numerical identifier with the aid of chaotic circuits or some other means of random number generation, at the central processing site of the ground segment. It is via this random process that polled transmissions of chemical data will be transmitted. At the conclusion of each polled transmission of remote chemical data to the LEO satellite, as earlier stated in section 2, there is a 0.3-s window of opportunity through which yet-to-be-polled remotes may transmit their chemical data from contaminant-exposed sensors to the available LEO satellite. Such sensors must include a “1” pre-empt bit in their overhead bit sets, if the immediately following chemical sensor data is not to be discarded at the LEO satellite. For the sake of illustration, if a “0” pre-empt bit accompanies an overhead bit set, its associated chemical sensor data set will not be transmitted to the nearest LEO satellite on an out-of-turn basis. This chemical sensor data set will instead be transmitted, with its “0” pre-empt bit, only when its sensor has been polled in the polling sequence.

To further illustrate this point, let us presume hypothetically that sensor #1 has been polled, and is transmitting nonhazardous chemical data to the LEO satellite overhead. At the same instant, however, sensor #29 in the same satellite coverage zone has detected hazardous chemicals in its vicinity. Sensor #29 therefore initiates contact of a pre-emptive nature with the available LEO satellite, to pre-empt the polling process, and thereby postpone the transmission of nonhazardous chemical data to the LEO – in favor of hazardous chemical data, which is instead transmitted to the LEO, and then to the central processing site at the ground control station – during the 0.3-s window subsequent to sensor #1’s transmission to the available LEO.

As soon as sensor #1 completes its transmission of nonhazardous chemical data to the LEO overhead, sensor #29 will begin its conveyance of hazardous chemical data to the same LEO. From the LEO this hazardous chemical data is relayed to the hub, or ground control station, where the central processing facility identifies the chemical, its concentration, and what, if any, protective measures and/or disposal actions should be taken in the vicinity of sensor #29. As soon as sensor #29’s chemical data has been conveyed to the ground station for further processing, the available LEO satellite in the same satellite coverage zone resumes the polling sequence at the sensor following sensor #1 in that satellite’s randomized polling sequence.

An available LEO satellite’s designated objective is to ensure that no single sensor is ignored in the LEO satellite’s quest for hazardous chemical data as it passes over a satellite coverage zone. In the foregoing illustration the pre-empt bit, a constituent bit of the overhead bit set for one of the chemical sensor data sets in the satellite coverage zone, becomes in essence a priority classifier. If the priority of the transmitting sensor is “0”, the polling sequence can be modified by a sensor whose pre-empt bit value, i.e. priority value, is “1”. When such an event occurs, the chemical data transmission associated with the “0” pre-empt bit is completed, at which time “1” pre-empt bit’s chemical data is transferred, to be followed by a resumption of the polling sequence. On the other hand, if a remote chemical sensor with pre-empt bit value “1” is transmitting, its transmission cannot be interrupted by another sensor of priority one until transmittal of its hazardous chemical data is complete. This prioritization of the polling sequence, according to the value of a chemical sensor data set’s pre-empt bit value, is the quality that renders this polling process “adaptive”.

Presuming this WAN’s design precepts are economy, disposability, performance, simplicity of design, and reliability, each LEO satellite will be designed in such a way as to yield worldwide coverage with 100% satellite availability, but with the minimum number of LEO
CHEMICAL-SENSING NETWORKS: SATELLITE-BASED

satellites. This goal appears to have been achieved here, and the critical orbital parameters for such a mission, have been earlier portrayed both in section 2 and on Figure 1 of this article. Other considerations essential to achieving the desired communications, and drawing clear conclusions from the communication of these chemical data at the ground station’s central processing site, will be discussed in the succeeding three sections.

6.4 Summary of Techniques

In summary, the random-access technique has many drawbacks associated with its potential application to this remote, chemical-sensing WAN, most evident of which are the high power and bandwidth requirements, high cost, unwieldy size as a result of high power needs, and resultant high weight of communications equipment that would be needed at both the receiver/transmitters for remote chemical sensors and at the 12 LEO satellites. These disadvantages render the random-access transponder the least attractive of the three candidate transponder access methods. Although having some advantages from the standpoints of confidentiality, difficulty of detection, low probability of intercept, and resistance to jamming, the complexity of CDMA receivers will pose problems with regard to cost. More importantly, however, this transponder would be used in peacetime, rather than military, applications. In addition to excessive cost associated with spread spectrum equipment for this application, the high bandwidth required by the DS CDMA transponders may result in undesired weight and size. Therefore, the DAMA, adaptive polling transponder would without a doubt be the most attractive of the three transponder candidate types for a disposable, chemical-sensing, nonmilitary WAN application.

7 SELECTION OF MODULATION TECHNIQUES APPROPRIATE TO THIS SERVICE

The most critical cost constraint in the configuration of this remote, chemical-sensing network, is the matter of determining how best to limit the cost of remote, chemical sensors – while at worst realizing only mildly discernible degradations in performance. The remote sensor will necessarily be power-limited, and its detector be of simple envelope detector type. Our selection of modulation techniques should complement both these remote design criteria. A spectrally efficient digital modulation scheme would be prudent for the remote transmitter, owing to its power-limited quality. Similarly, an envelope detector provides economical receiver function. Fortunately, both these remote design criteria are realizable when coherent BPSK\(^{(5,17)}\) data are sent from each chemical remote’s transmitter, and noncoherent FSK transmissions from the available LEO satellite are received at each polled, remote sensor’s envelope detector in that satellite coverage zone.

8 CHOOSING A LONG-LIVED, RELIABLE, POWER SOURCE FOR THE REMOTES

After consultations with various vendors of lithium/manganese dioxide batteries, it was concluded\(^{(18)}\) that for a duty cycle of less than 50%, in this case, 1%, 3 W power can be delivered by just such a small battery. Vendor performance curves have verified that use of the lithium/manganese dioxide batteries to power remote chemical sensors is indeed reasonable. These power levels for remote transmissions will provide more than sufficient link margins of 4.8 dB or more for this application, according to link results in Table 1.

9 FEASIBILITY ANALYSIS OF THE PRESCRIBED WIDE AREA NETWORK REALIZATION

All engineering analyses pertaining to this remote, chemical-sensing satellite configuration indicate that such a WAN, as described both in the abstract overview of the Introduction and in more elaboration on the foregoing pages, is entirely realizable. More importantly, such a chemical, remote-sensing WAN has been modeled, and should perform effectively, even with the imposition of ambitious cost and performance constraints. These results show that for confidential, commercial and/or public applications this network is more than acceptable. In a military scenario, in the presence of potential jamming and low-power transmissions, it is entirely possible that this WAN, working in tandem with chaotic circuits

\]
for enhanced security of operation, could satisfy some military communications standards. However, determination as to whether the communication methods outlined above are appropriate for military application would require large amounts of time and planning, money, engineering in the design, development, and test of computer simulations and/or hardware prototypes. Quantifying and evaluating precisely to which standards of military security the proposed WAN might conform is certainly a worthy topic for follow-on engineering research and analysis, but, once more, is beyond the scope of this article.

The two figures and three tables of this document also serve to confirm the feasibility of the proposed remote, chemical-sensing WAN. For example, Table 1 demonstrates that the satellite links with SAW sensors, with IMS sensors, or underground SAW sensors connected via OF links to receiver/transmitters on the earth’s surface, all provide more than adequate link margins (at least 1.5 dB) of 4.88 dB or more. Consequently, the abovementioned WAN for remote, chemical-sensing, as described approximately herein, appears to be viable. Table 2 offers some essential equations used in the feasibility modeling of the proposed WAN, such as those equations used in the computation of link budgets and link margins – replete with probability of bit error equations for noncoherent FSK digital modulation on the polling link and coherent BPSK digital modulation on the return link. Table 3 tabulates the majority of numerical values required in the solution of the equations in Table 2, e.g. powers of transmission, antenna gains, noise temperatures, data rates on links, presumed levels of fading and backoff, slant range, and Boltzmann’s constant. The equations of Table 2 and the numerical data from Table 3 were then implemented in the computation of link budgets, and the resulting link margins offered in Table 1. It has been presumed that these links are designed for commercial applications, with prospects for the occurrence of jamming interferences viewed as remote, and, as a result, concluding that a link margin of 1.5 dB or greater is sufficient.

1 Introduction

The development of rapid, cost-effective, accurate methods for environmental site characterization and monitoring has been a very active area of research during the past two decades. One approach that has recently received widespread attention involves the use of cone penetrometer technologies for in situ detection and mapping of environmental contaminants in subsurface soils and groundwater. The most recent technological developments include the incorporation of on-line analytical and in situ chemical detection techniques into the cone penetrometer. This article describes a variety of sampling and chemical sensing technologies that have been or are currently being adapted to cone penetrometer systems for the detection of subsurface contaminants, including petroleum, oils, and lubricants (POLs), volatile organic compounds (VOCs), toxic metals, explosives/energetics, and radioactive wastes. For example, cone penetrometer devices that incorporate in situ isolation techniques to purge VOCs from groundwater eliminate the analysis of the sample media in the laboratory. A high level of agreement was found between an in situ purging technique and the conventional method of bailing a sample from a groundwater sampler, transferring the sample to a container, and analyzing the sample in the laboratory. Completion of a site characterization with this probe was estimated to require approximately 15% of the time needed for conventional methods, significantly reducing costs. The laser-induced fluorescence (LIF) sensor, which measures POLs, represents the first and most mature cone penetrometer chemical detection technology. Technology evaluations estimated that costs of site characterizations using the LIF probe are approximately 30% lower than costs of site characterizations using conventional methods for collecting soil cores, subsampling the cores, and analyzing the subsamples in the laboratory.

1 INTRODUCTION

The traditional methods for determining the location and levels of subsurface chemical contamination in widely varying types of soil and groundwater are time-consuming and costly and often result in less than adequate site characterization. Conventional environmental site investigations require installation of many monitoring wells and subsequent analysis of discrete soil and groundwater samples by using standard laboratory methods. Samples are often collected without any a priori knowledge about the exact location and extent of contaminant plumes. Zones or plumes of contamination can be completely missed or over- or underestimated. Effective site characterization is often hampered by the inability to select optimal locations for monitoring wells. The locations of the monitoring wells are usually based on information gleaned from site historical data, groundwater hydrology, or indirect chemical screening by measuring volatile contaminants in soil gas or some combination of the three. Because of uncertainties in the available information, placement of monitoring wells is at best an inexact science; historical data are often incomplete or inaccurate; knowledge of groundwater hydrology at the site may not provide the level of detail required to understand site characteristics; and interpretations of soil gas measurements may...
be complicated by erratic movement of vapor in the soil due to impervious layers and changes in atmospheric temperature and pressure. Consequently, many wells are not properly positioned and, therefore, yield information of marginal utility. Furthermore, the ability to resolve horizontal and vertical features in the distribution of chemical contaminants is limited by the spacing between wells and the vertical spacing between samples. Accurately delineating the boundaries of contaminant plumes and defining small-scale vertical structure in the distribution of contamination have important implications with respect to site remediation. The more precisely the area of contamination is defined, the less likely it is that clean material will be unnecessarily removed or subjected to costly remediation procedures. Such an approach can be prohibitively costly and labor intensive when conventional techniques are used. In addition, in a number of subsurface environments, the delay from sample collection to interpretation of laboratory analyses can severely hamper the response time and can hinder contaminant containment, possibly resulting in a much larger extent and expense of cleanup.

As a result of these shortcomings, much current research has focused on the development of rapid, cost-effective in situ techniques to monitor both organic and inorganic pollutants. These new methods provide a thorough mapping of contaminated areas by being able to sample the subsurface with high spatial resolution. This mapping makes it possible to rapidly interpret the extent and location of contaminants and efficiently plan and direct cleanup operations. Furthermore, in situ methods minimize the risk of sampling artifacts and can be performed in hostile environments without exposing personnel to toxic contaminants.

One technology that is gaining widespread acceptance for rapid environmental site characterization involves the use of cone penetrometer systems. The electronic cone penetrometer test (CPT) was developed to provide detailed geotechnical information on the subsurface. By combining the results of the CPT with a detailed chemical characterization of the groundwater, soil, and soil gas, the migration of subsurface contaminants can be investigated. Many sampling and sensing technologies have been interfaced with the cone penetrometer to provide a chemical characterization of the subsurface. These sampling and sensing technologies provide near-real-time quantitative or qualitative data or both of subsurface chemical contamination with high spatial resolution. The devices include samplers that collect water, soil, and soil gas from the subsurface. The medium is typically transferred to an inert container and returned to the laboratory for analysis. For some analytes, particularly VOCs, these transfer steps can lead to incomplete recoveries of the chemical substances and erroneous results. On-line analytical techniques that include an in situ isolation of the chemical substance from the subsurface media in the cone penetrometer and a direct transfer of the analyte to an instrument or chemical sensor at the surface are being developed to eliminate these transfer steps. In a more direct approach, chemical sensors have been interfaced with the cone penetrometer to perform an in situ analysis of the subsurface media, thereby eliminating the isolation and transfer steps of the on-line analytical techniques.

The Site Characterization and Analysis Penetrometer System (SCAPS) was initially developed by the US Army during the late 1980s and at that time was the first cone penetrometer system specifically designed for rapid environmental site characterization. The SCAPS (Figure 1) is based on a custom-engineered 20-ton truck capable of hydraulically pushing an instrumented probe to a maximum depth of 50 m. The truck houses two separate, protected work spaces to allow access to contaminated sites with minimal risk to the work crew. One of the work spaces contains the penetrometer tool, the push pipe, and hydraulic controls for leveling the truck and advancing the penetrometer tool. The other work space houses optical systems, chemical analysis equipment, and the equipment for digital data acquisition, processing, and display. The penetrometer unit can be equipped with a number of sensors and samplers designed to detect a variety of classes of subsurface contaminants, including POLs, VOCs, metals, explosives,

Figure 1 Typical CPT system for environmental site characterization and monitoring. (Courtesy of the US Army Corps of Engineers Waterways Experiment Station.)
and radioactive wastes. Incorporated into the SCAPS rig, and also into a number of other cone penetrometer units, is equipment for decontaminating the push rods as they are being retracted that consists of rubber wipers and steam cleaning equipment mounted under the push room. As the push rods are retracted following a cone penetrometer push, the rods are scrubbed and steam cleaned, and the wastewater is collected for off-site disposal. Also incorporated into a number of cone penetrometer systems is equipment that allows for grouting of the hole during probe retraction to prevent any migration of contaminants. The SCAPS trucks are currently being operated by the United States Department of Defense (USDOD), the United States Department of Energy (USDOE), the United States Environmental Protection Agency (USEPA), and private industry to conduct site characterization tasks. The various sensors and samplers used on SCAPS and similar cone penetrometer systems are described in subsequent sections.

2 CONE PENETROMETER TESTING

The CPT is used to gather geotechnical information on the subsurface. Mechanical cone penetrometers were developed in the early 1900s to identify strong soil layers for the design of pilings and building foundations. The mechanical CPT provides a discontinuous record of geotechnical properties at shallow depths. The electronic cone penetrometer was developed in the 1960s to examine accurately soil stratigraphy at depths approaching 90 m. The electronic cone penetrometer, which consists of an instrumented conical probe (cone) and 1-m sections of metal pipe (rods), is advanced with hydraulic jacks from a skid- or truck-mounted rig that can weigh between 20 and 40 tons. The maximum thrust the rods can withstand is 45,000 lb force (200 kN). This thrust will advance the cone to 30 m in stiff material and as much as 80 m in looser soils. The probe is advanced in 1-m intervals at 1–2 cm s⁻¹ and is interrupted at each interval to attach additional rods to the top of the string of rods in the cone penetrometer truck. The electronic CPT represents a continuous record of the resistance to penetration.

The cone consists of a hollow steel rod that is 3.0–4.1 cm in outer diameter (OD) [2.5-cm inner diameter (ID)] with a 60° conical point and a friction sleeve that is 13.3 cm long. Several sensors located in the cone are connected to an automatic data recording system in the cone penetrometer truck by an electrical cable that runs through all of the rod sections. Strain gauges located behind the tip and friction sleeve measure the displacement associated with the resistance to penetration. The tip resistance is a measure of the total stress or intergranular pressure plus water pressure, and the friction resistance is the sum of friction and adhesion. The ratio of these two resistances is used to determine soil type and to derive a stratigraphic log of the CPT. Soil classification by using the CPT is empirically based. The classification differentiates gravel, sand, silt, clay, some intermediate soil types and some overconsolidated soils. The American Society for Testing and Materials (ASTM) standard D 3441-86 is used to ensure uniformity with regard to the cone characteristics, calibration, and testing and reporting procedures.

The cone can contain several other sensors for measuring parameters that are useful in interpreting the migration of subsurface contaminants. Dynamic and equilibrium pore water pressures are measured by using a porous stone filter in the cone that is connected to a pressure transducer. A probe to determine soil moisture has also been developed. Sensors to measure the inclination are used for correcting depth to the lateral drift of the cone. Electrical conductivity sensors and nuclear and seismic probes have also been used in the cone penetrometer. Soil resistivity can be used as a rough measure of the contamination of the soil. The hydraulic conductivity, hydrostatic head, independent soil classifications, and soil permeability can be derived from measurements obtained from these additional sensors.

3 SAMPLERS

Many samplers have been interfaced with the cone penetrometer to perform an in situ collection of groundwater, soil, and soil gas. Following sample collection, the soil and groundwater probes are usually brought to the surface, and the sample is transferred to a container and analyzed on-site or transported off-site to a laboratory for analysis. Soil gas probes directly transfer the gas from the probe through tubing to a container or gas analyzer at the surface. Careful attention must be paid to the materials that are used in the device and in the sample container so that the media is not contaminated or the analytes are not sorbed to the device or container. Groundwater and soil gas are typically sampled through a porous element in the probe. Soil cores are collected in liners located in the rods of the penetrometer. The soil cores can be retrieved and subsampled in the field, or the ends of the liner can be capped and the entire core returned to the laboratory.

3.1 Groundwater

Several different designs have been used for cone penetrometer groundwater samplers. One of the common features of the designs is a porous element through which the groundwater must pass before it enters a sample chamber or container. The filter is typically covered by a
retractable shield that protects it from contamination during the cone penetrometer sounding. Groundwater enters many of the devices under ambient hydrostatic pressure; however, some samplers are capable of applying a slight vacuum to aid in the collection of the sample.

Wellpoint batch water (WBW) samplers have been used for many years and are designed to collect large volumes of groundwater. The WBW sampler designed by Hogentogler & Co., Inc. (Columbia, MD, USA) has a stainless-steel point that is attached to a rod section containing a slotted stainless-steel screen. The screen can be either exposed or protected by a sleeve. A sampler with an unprotected screen can be used at several depths; however, the filter may become contaminated during the push. A sampler with a protective sleeve is pushed to the desired depth, and the rods are retracted to expose the filter. Water samples are retrieved with a bailer, or the sample chamber can be pressurized and the sample retrieved from another line, or the entire probe can be retrieved and the sample poured out of the tip.

Two designs of the HydroPunch™ (QED Environmental Systems, Inc., Ann Arbor, MI, USA) have been used for groundwater sampling. The sample chamber of the HydroPunch™ has a capacity of 500 mL and is constructed of stainless steel and Teflon®. A shielded section of perforated stainless-steel pipe is used as an intake. A disposable polypropylene screen covers the water intake in the sample chamber. To retrieve the sample the rods are retracted so that two Teflon® check valves close and retain the sample in the chamber. At the surface, the upper check valve is replaced with a stopcock and a disposable tube, the sampler is turned upside down, and the sample is transferred to an appropriate container. The sample chamber of the HydroPunch II™ has a capacity of 1250 mL and is constructed of stainless steel and Viton®. Unlike the HydroPunch I™, this sampler is capable of collecting pools of organic contaminants that are less dense than water. The sample intake consists of a shielded 125-µm, 120-mesh stainless-steel screen. Poly(vinyl chloride) or polypropylene screens can also be used with the sampler. A bailer is lowered through the rods and into the sample chamber to retrieve the sample. At the surface, the water is transferred from the bailer to another container. A sampler similar to the HydroPunch™ has been designed that uses a 250-µm polypropylene porous filter as the water intake [Applied Research Associates, Inc. (ARA), South Royalton, VT, USA]. The sample can be retrieved with a Teflon® or stainless-steel bailer or can be pumped to the surface with a double-valve pump.

The Hydrocone™ (In Situ Technology, Orlando, FL, USA) consists of a sampler body with a shielded, telescoping porous tip. The sampler is pushed to depth and then retracted, exposing the porous frit to the groundwater. The rate at which the sample chamber is filled is monitored by a water level sensor and controlled by maintaining a balance between the natural hydrostatic pressure and a variable argon gas back-pressure. This process also minimizes the amount of volatilization that may occur for some organic analytes during sample collection. The Hydrocone™ is retrieved, and the sample is decanted from the sample chamber. The Hydro Trap™ sampler (Fugro Geosciences, Inc., Houston, TX, USA) is designed similarly to the Hydrocone™ and uses a shielded stainless-steel screen as a porous element.

The BAT™ sampler (Figure 2a–c) has a stainless-steel drive point with a stainless-steel body and retractable sleeve. The probe is driven to the desired depth, and the stainless-steel sleeve is retracted, exposing a filter tip to the groundwater. Filter tips of high-density polyethylene (HDPE), sintered ceramic, and porous polytetrafluoroethylene (PTFE) were originally designed for the system, although Type 316 stainless-steel filters have also been used. The sample chamber has a double-ended hypodermic needle connection. A sampling probe containing a pre-evacuated vial with a septum-lined cap is lowered to the sample chamber and pierced by the needle, forming a leak-tight connection with the sample chamber. The sample is collected under in situ hydrostatic pressure. The vial is retrieved, making it unnecessary to transfer the sample to another container.

The Cone-Sipper™ (ARA) is able to collect samples at multiple depths during a single penetrometer push and is able to accommodate the electronic cone. A specially designed two-stage filter that is exposed during the penetrometer sounding removes coarse- and fine-grained materials from the water (Figure 3). Water is drawn into lower and upper sample chambers by using a combination vacuum/pressure line. The two chambers are separated by a ball check valve. During the pressurization cycle, the check valve prevents water from returning to the lower chamber while water is being drawn from the upper chamber to the surface through Teflon® tubing. The water can be collected in vials at the surface, or the Teflon® sample line can be directly connected to the purge vessel of a purge-and-trap concentrator to provide an on-line analytical capability. The sampler is cleaned between sample collections by pressurizing the device with an inert compressed gas and purging the system out through the filter. Distilled water is then forced through the system in an additional cleansing step.

3.2 Soil

The Gouda™ and the MOSTAP™ samplers were originally developed to be used with the cone penetrometer to obtain soil cores for geotechnical analysis and are currently used to collect soil cores for chemical analysis.
The basic differences between the two devices are their disengagement mechanisms and the size of the soil cores that they are able to retrieve. The Gouda™ sampler isolates a soil core that is 25 × 195 mm (~95 cm³), and the MOSTAP™ sampler collects a soil core that is 38 × 520 mm (~1924 cm³).

The GEOSTAR™ soil samplers (Hogentogler & Co., Inc.) can retrieve soil cores that are 24 × 175 mm and 25 × 200 mm (Figure 4). The samplers are completely sealed with O-rings while the probe is pushed to depth. The rods are then retracted about 18 cm to withdraw the hardened stainless-steel tip into the body of the sampler, expose the cutting edge, and lock the device into the open position. The cone penetrometer is then advanced to collect the soil core. A vent in the top of the sample barrel is open during the push and then closed when the sample is retrieved to hold the sample in the liner. Fugro Geosciences, Inc. (Houston, TX, USA) also use a soil sampler that has a stainless-steel split barrel for retaining the soil core.

A soil sampler developed by ARA retains a soil core that is approximately 35 × 600 mm. The soil sampler is pushed to the desired depth and a tip release bar is lowered by a cable through the rods. The sampler is retracted to relieve the pressure at the tip and then the cable is pulled up to release the tip. The release bar is then pulled up and dropped on to the tip assembly. This action releases the latches and engages the tip release bar. The cable is then pulled up and the latches are disengaged from the tip release bar. The sampler is then advanced by pushing on the cone penetrometer rods to fill a metal or plastic sample tube. A split metal tube may also be used in the sampler. Upon retrieval of the sample barrel, the sample tube may be capped, or the sample may be extruded from the tube. Samples obtained with the split sample tube may be subsampled. An additional benefit of the sampler is the ability to stack the sample barrels to double the length of the core that can be collected.

3.3 Soil Gas

Soil gas is sampled within the vadose zone of the subsurface. The gas enters a port in the sampler.
and is drawn through tubing to the surface by applying a vacuum. For VOC analysis, the sample is collected in a polymeric bag, glass bulb, or stainless-steel canister. The sample may also be concentrated on a solid sorbent or pass directly into a gas analyzer.

The Cone Penetrometer/Vadose Zone Vapor (CP/VZV™) probe consists of a hollow barrel covered with a porous material that is positioned 46 cm above the tip of the cone. The hollow barrel serves as a gas collection zone that is connected to an organic vapor meter or a field-portable gas chromatograph at the surface by Teflon® tubing. The BAT™, Cone-Sipper™, and HydroPunch™ devices can also be used for the collection of soil gas. Soil gas is efficiently collected in the preevacuated vial of the BAT™ sampler. In the Cone-Sipper™, a vacuum pump is attached to the vacuum line of the probe, and a sampling container or gas analyzer is attached to the vent tube to collect or analyze the sample. The pressurized line allows the sampler to be purged in between sample collections. The HydroPunch™ can also be operated similarly for the collection of soil gas. Samples that use a two-line vapor sampling design to purge the vapor transfer lines between sample collections have also been developed.

The multiport sampler (MPS), developed by the United States Army Corps of Engineers Waterways Experiment Station (WES) and shown in Figure 5, has 12 vertically stacked sampling modules that are independently operated from the surface to collect multiple vapor samples during a single penetration.
The MPS is advanced to the desired sampling depth, a module is selectively opened, and analyte is drawn through a sidewall port. An applied vacuum is used to open the ports and draw the sample through nylon tubing to the surface directly to an analytic instrument or to a solid sorbent to concentrate the sample. Replicate samples can be collected at a single depth, and different ports can be used during depth profiling to prevent cross-contamination of samples. In addition to the sampling modules, the MPS is capable of real-time soil stratigraphy mapping and also of grouting through the probe tip as the MPS is retracted to prevent cross-layer contamination. The MPS has been successfully used to sample vapors from soils contaminated with chlorinated organic solvents to determine the relative concentration of the contaminants in different soil strata.

4 ON-LINE ANALYTICAL TECHNIQUES

On-line analytical techniques have been interfaced with the cone penetrometer to quantify VOC and semivolatile organic compound (SVOC) contamination of the subsurface. These techniques include isolation, preconcentration, transfer, and chemical detection steps. This section will focus on the first three steps of the method, and chemical detection techniques will be discussed in section 5.

In situ isolation techniques have been developed to eliminate the transfer of groundwater, soil, and soil gas from in situ sampling probes to a container prior to chemical analysis. Erroneous results have been found, particularly for VOCs, when this transfer step is included in the sampling technique. Following the isolation step, the organic contaminants can be concentrated at depth, analyzed in situ by a chemical sensor or instrument, or transferred through tubing to a chemical sensor or instrument in the cone penetrometer truck. Laboratory methods have been developed to isolate organic analytes from groundwater and soil by water purging and thermal desorption (TD) techniques, respectively. Cryogenic preconcentration, solid sorbent preconcentration methods, solid-phase microextraction, and membrane extraction techniques have all been used to preconcentrate the analyte before analysis. The analytes may also be transferred directly from the isolation probe to an instrument or chemical sensor at the surface. This technique allows for multiple sample collection from a single penetrometer push provided that the porous element can be cleaned between sample collections; however, a critical aspect of the on-line techniques is the quantitative transfer of analytes from the sample probe to the instrument or chemical sensor at the surface through tubings that can approach 100 m in length.

4.1 Isolation Techniques

Several samplers have been developed for the cone penetrometer that use TD to isolate organic analytes from soil. The thermal desorption sampler (TDS) incorporates a TD system into a custom-designed soil sampler. The TDS consists of a series of concentric steel cylinders with gas channels and piston chambers that are sealed by O-rings (Figure 6a and b). The probe is activated from a center actuator rod that is held in place by locking lugs. The device is pushed to depth, the lugs are pneumatically released, the piston is retracted to open the sample chamber, and the probe is advanced to capture a small plug of soil of known volume in the chamber. The chamber is heated to 150 °C by a Nichrome-wrapped ceramic heater that is protected with a stainless-steel sleeve. A thermocouple is used to monitor the temperature of the sample chamber. Preheated purge gas enters the sample chamber through the annular space between the outer housing and the actuator rod housing. The volatilized organics are transferred through the center of the actuator rod. The TDS was evaluated in the laboratory with soils to which chlorinated aliphatic hydrocarbons, aromatic hydrocarbons, and chlorinated aromatic hydrocarbons were added. Sand, silt, and clay soils containing 10 and 20% water were used in the laboratory tests. Analyte recoveries were all greater than 80%.
but they were significantly lower in silt containing 20% moisture than in clay containing 10% moisture or in a mixture of sand and silt containing 10% moisture. Recoveries for benzene, trichloroethene (TCE), toluene, and chlorobenzene were 87, 87, 95, and 89%, respectively, and reflected the efficiency of drying the soil during TD. At 100 °C, the sampler effectively dried soils with moisture contents up to 17%.

Several devices have been developed to isolate VOCs from groundwater by an in situ purging method. Design considerations for in situ purge devices (ISPDs) have been presented. An in situ device for purging

The Thermal Extractor for the Cone Penetrometer (TECP™) has been developed as a TD device for SVOCs in soil. Cartridge heaters are used to heat the soil adjacent to the surface of the probe to approximately 250 °C. The sample ports are covered with stainless-steel disks (20 µm). The SVOCs are volatilized from the soil during a 4-min TD step as a vacuum is applied to the sample ports to facilitate transfer of the analytes. Similar to the TDS™, recoveries of SVOCs from the TECP™ are highly dependent on the efficiency of heating the soil adjacent to the probe. Laboratory investigations with soil containing a moisture content of 22% with the cartridge heater temperature set at 450 °C indicated that the temperature of the 20-cm long probe was 400 °C. Under these conditions, a maximum temperature of 250 °C was attained in the soil at a distance of 2 mm from the probe. The zone of collection is estimated to be approximately 2 cm³. The volume of soil that is analyzed by the TECP™ has to be estimated because, unlike the TDS™, a known volume of soil is not captured by the device. Laboratory evaluation of the TECP™ using dry sand containing a mixture of polycyclic aromatic hydrocarbon (PAH) compounds, organochlorine pesticides, and polychlorinated biphenyl (PCB) compounds at 12, 15, and 28 ppm, respectively, indicated that recoveries for these SVOCs were 60–90%. The TD efficiencies decreased as the moisture content increased because of a decrease in the heating efficiency of the probe. At a moisture content of about 20%, recoveries were 35–50% from sand. Recoveries of 20–40% were achieved with a fortified soil sample containing 10% moisture and were a few percent lower in a coal tar sample containing 13% moisture. Estimated detection limits of the device are approximately 500 ppb by cryogenic preconcentration TD/GC/mass spectrometry (MS).

ARA developed the Dynamic Thermal Desorption™ (DTD™) probe to desorb VOCs from soils of the vadose zone. The DTD™ probe contains a heating sleeve and a specially designed sampling port. The sampling port is covered by a screen consisting of a lengthwise slotted steel sleeve that is backed by a sintered steel filter, identical with the filter of the Cone-Sipper™. The slotted steel sleeve protects the sintered steel filter during the penetration and the sintered filter keeps fine material from blocking the port. The heater is composed of a heating sleeve, a heating wire, and a thermal insulator. The heated sleeve warms the soil ahead of the sample port to volatilize the VOCs. The heated soil gas is continuously drawn through the sample port and into the probe by vacuum.
VOCs from groundwater in monitoring wells has been developed in which water enters the sample chamber in the device through a sintered metal filter in the base of the chamber and a normally closed solenoid valve. The top of the chamber is vented to the atmosphere. Several different methods were evaluated to detect the level of water in the sample chamber and initiate the purge cycle. The filling sequence is initiated by opening the valve on the top of the chamber. The level-sensing circuit is made up of three electrodes: one electrode at the base of the sample chamber, a second electrode slightly above the base, and a third electrode near the top of the chamber. A potential difference is applied between the base and the other two electrodes and the current flow is monitored. The valve is closed once a current is detected. Other level-sensing devices that were proposed included pressure switches, optical monitoring, and mechanical floats. The sample is purged by pulling a vacuum on the system through a sorbent tube to trap the volatile compounds.

The ISPD integrates a miniaturized purge device with the cone penetrometer. The purge device is machined as four separate Type 316 stainless-steel sections (Figure 7). The sample section contains the purge chamber, purge line (with 60-µm porous sintered nickel frit), conductivity level sensor, and connection for the transfer line. The insert sleeve contains the mixing and purge line inserts. The mixing insert positions the purge line at the base of the water in the sample section. The inlet section aligns the mixing insert connection to two miniature electrically actuated two-way valves. A hole large enough to house the connections for the CPT runs through the purge device. A proprietary frit (Bladon International, Oak Brook, IL, USA) is used as the groundwater inlet. Thevalving is controlled from the surface and consists of miniaturized valves that are also connected to a conductivity detector that closes a valve when a 5-mL volume of groundwater has entered the sample chamber. The purge cycle is initiated and the analytes are transferred to the surface through stainless-steel tubing that is heated to 50 °C. The analytes are either collected on a sorbent cartridge or transferred directly into an instrument for analysis. The advantages of this technique are that (1) a known volume of groundwater is purged and (2) the sampler can be used for depth profiling. Laboratory testing and preliminary field testing of the device have been completed.

Laboratory testing of the purge device was performed with a mixture of halogenated aliphatic hydrocarbons and aromatic hydrocarbons at levels of 1–1000 ng L⁻¹. Recoveries were all >90%, with <1% carryover between samples. Evaluations of the device in a monitoring well indicated that the sampling precision and carryover were 14% and <5%, respectively, for groundwater containing 420 ppb of 1,1-dichloroethane. In another field test, good agreement was found for samples collected from a nearby monitoring well with a bailer and for samples analyzed in situ by the ISPD. The CISP probe developed by ARA is similar to the ISPD, with the exception of cis-1,2-dichloroethene, which was much higher in samples analyzed by the ISPD.

The cone penetrometer in situ purging (CISP) probe developed by ARA is similar to the ISPD. The CISP probe obtains a sample by allowing a fixed volume of groundwater to enter a stainless-steel chamber in the probe through a normally closed solenoid valve. The sample is driven from the soil into the probe by ambient pressure.
hydraulic pressure and is purged with nitrogen. A two-stage filter is used at the inlet, which has a slotted sleeve and sintered screen that is the same as the inlet used with the Cone-Sipper™. A conductivity level sensor is used to initiate the purge cycle.

The Hydrosparge™, developed in a joint effort between Oak Ridge National Laboratory (ORNL) and WES, is a miniaturized purge device that is designed to be used with the HydroPunch™ and PowerPunch™ samplers (GeoInsight, Clayton, CA, USA) to isolate VOCs from groundwater. The PowerPunch™ is based on the design of the HydroPunch™ and is used to insert small-diameter monitoring wells by using the cone penetrometer truck. The device is capable of rapidly obtaining large volumes of water because of its adjustable screen length. Water is allowed to enter the cavity of the sampler, and the level is monitored with a conductivity sensor. The Hydrosparge™ is lowered into the sampler after the water level has become stable. The analytes are purged from the groundwater and transferred to the surface through Teflon® tubing.

Other techniques have been used in the laboratory for the isolation of VOCs from soil and groundwater but they have not been interfaced with the cone penetrometer. These techniques include the spray-and-trap method and headspace analysis. The spray-and-trap method employs dynamic stripping of the VOCs by gradually spraying the water sample into a recipient vessel through a surface expansion nozzle. The time required for complete extraction of VOCs is about 4 min and is less than the 11 min recommended for complete extraction by the purge-and-trap technique. In addition, unlike the purge-and-trap method, the spray-and-trap method can efficiently isolate VOCs from waters containing surfactants. Headspace analysis has been applied to soil and groundwater samples, but an in situ device that employs this isolation technique has not been developed. The technique relies on an accurate determination of the VOC concentration in the gaseous headspace and the use of Henry’s law to determine the concentration of the VOC in the aqueous phase. The Henry’s law constant is the ratio of the equilibrium concentration of an analyte in air above an aqueous phase to its equilibrium concentration in the aqueous phase. The Henry’s law constant is approximated as the ratio of a compound’s vapor pressure and its aqueous solubility. Consequently, an analysis of the concentration of an analyte in the gaseous headspace can be used to derive the concentration of that analyte in the aqueous phase from the Henry’s law constant. For groundwater samples, the analysis is straightforward; however, for soil samples, the soil would have to be immersed in an aqueous phase and vigorously mixed prior to sampling of the headspace. This procedure may be too complicated to interface with the cone penetrometer.

### 4.2 Preconcentration Techniques

Organic compounds in soil, soil gas, and groundwater are typically preconcentrated before analysis. Several methods have been used for this purpose and include cryogenic and solid sorbent preconcentration, solid-phase microextraction, and membrane extraction techniques. These techniques can be coupled with the in situ isolation techniques to provide an on-line analytical capability for the cone penetrometer.

Organic analytes are cryogenically preconcentrated at subambient temperatures on solid substrates such as glass, fused silica, or quartz wool and on solid, fused-silica, or porous-silica glass beads. For VOCs and SVOCs, the solid substrate is typically cooled to −190 and −60°C, respectively. These techniques typically use a two-position valve to direct gas flows during the trapping and desorption steps. A resistive heater is used to heat the substrate at rates of ~400°C min⁻¹ for efficient TD. A cryointegration technique has been developed that does not use sample loops or mechanical valves in the sample flow path. The sample is pulled through the cold trap with a vacuum pump that can operate from 20 torr to the pressure of the carrier gas. The trap is cooled from −100 to −200°C. The sample is drawn through the cold trap and is then desorbed while being backflushed. The sample trap is heated by capacitive discharge. Bare metal trap tubes consisting of a 15-cm length of 0.30-mm ID Cu (30%)–Ni (70%) alloy and porous polymeric adsorbent-lined trap tubes have been used. The adsorbent-lined trap tubes are used for the most volatile analytes. Organic analytes that are isolated from groundwater by purge-and-trap methods or from moist soils by TD in an inert gas may also contain significant amounts of water that may plug the cryogenic trap. One of the drawbacks of the cryointegration technique is that it is limited to a sample volume of about 2 mL for water-saturated air. Consequently, gas streams may require a Naﬁon® dryer to remove the water prior to cryogenic preconcentration. Cryogenic preconcentration devices are large and have not been miniaturized for use in the cone penetrometer; however, the devices can be directly interfaced to an instrument or chemical sensor at the surface as part of an on-line analytical method.

Solid sorbent methods have been used extensively to preconcentrate VOCs in gas streams. Typical sorbents include charcoal, Tenax®, graphitized carbon black, and mixtures of materials in the same sorbent bed. The hydrophobic nature of these sorbents prevents water from being collected in most applications, with the exception of the TD of some wet soils. Graphitized carbon black has been found to be suitable for a wide range of volatile organohalogenes in soil gas and Tenax® has been used to collect VOCs that have
been desorbed from soil. The ORNL arrayed sampler for collection of VOCs in soil gas uses multisorbent cartridges containing Carboplot, Carboplot C, and Carbosieve S-III (Supelco, Bellefonte, PA, USA). The sorbent can be located in either a sorbent tube in the cone penetrometer or in the Downhole Trap Module (DTM) (ARA), or at the surface directly interfaced to an instrument in an on-line analytical technique. The sorbent is usually thermally desorbed while backflushing with an inert gas. For applications where the sorbent contains an excessive amount of water, the sorbent can be extracted with a polar solvent, and an aliquot of the extraction solution can be analyzed.

The use of solid-phase microextraction techniques for the analysis of VOCs in soil and water by headspace analysis and for the analysis of water directly has been described in detail. Briefly, a fiber is coated with an organic phase that is similar to those used as stationary phases for GC columns. The fiber is allowed to equilibrate with the media and is analyzed by inserting it into the heated injection port of a gas chromatograph. The method has to be calibrated to determine the concentration of the analyte in the solid or aqueous phase. The method has not been interfaced with a cone penetrometer, but it may find some application for the headspace analysis of media isolated in the cone penetrometer.

Membrane extraction methods use membranes in the form of disks or tubings. Disk technology has been used for the extraction of SVOCs from water and air. PTFE disks enmeshed with 8-µm diameter C18-bonded silica have been used for the extraction of SVOCs. The analytes are eluted from the disk with a solvent. Silicone-rubber tubing has been used in membrane introduction mass spectrometry (MIMS) for selective transport of analytes into a mass spectrometer. Water that may interfere with the analysis is retained by the membrane. The technique has been used with success for the analysis of VOCs in water. In the laboratory, silicone-rubber membranes have also been suspended in the headspace above liquids and in the aqueous phase as an inert gas is passed through the tubing to extract the analytes from the media. This technique could possibly be used as part of an on-line analytical technique in, for example, the HydroPunch sampler, to extract VOCs from groundwater.

4.3 Transfer Techniques

Analyte transfer techniques are used to transport the analytes in an inert gas from the cone penetrometer to a chemical sensor or instrument at the surface. These techniques are necessary when the incorporation of preconcentration devices or chemical sensors and instruments into the cone penetrometer rods is not possible. The most critical aspect of the approach is the quantitative transfer of the analytes through tubing that can approach 100 m in length. The transfer line must be continuous and strung through all of the rods that are assembled for the penetrometer sounding. One end of the line is connected to the isolation device in the penetrometer and the other end is connected to the chemical sensor or instrument in the cone penetrometer truck. The positioning of the rods in the rack of the cone penetrometer truck requires that the transfer line be bent in a radius of 15 cm or less as it is strung from the end of one rod into the next rod. Consequently, the tubing must be rugged enough so that repeated bending and straightening will not crimp or break the transfer line.

Transfer lines of fused silica or glass-lined stainless-steel tubing are routinely used in the trace analytical laboratory to interface sample concentrators with analytical instruments. Passivated metal tubings [ProSteel® (J&W Scientific, Folsom, CA, USA); Ultimet® (Chrompack, Raritan, NJ, USA)] are now used to fabricate capillary columns for GC where ruggedness is a concern. For the analysis of VOCs in ambient air, samples are stored in passivated metal or fused-silica-lined canisters. Polymeric tubing such as Teflon would be advantageous for use in cone penetrometer applications because of its flexibility. The transfer line materials must be inert to the analyte of interest. The transfer line must also be heated to a temperature that can maintain the analytes in the vapor state and prevent the condensation of water in the tubing. Condensation may sorb water-soluble analytes and restrict the gas flow. For VOCs, heating the tubing to a temperature above the dew point of water at the sub-surface temperature may be sufficient. For SVOCs, the tubing must be heated much higher (>200 °C) to maintain the analytes in the vapor phase.

Various metal (e.g. stainless steel, aluminum, and nickel) and polymeric tubings (e.g. Viton® (polyvinylidene fluoride hexafluoropropylene), nylon (polyamide), Tefzel® (ethylenetetrafluoroethylene), PEEK (polyether ether ketone), and also Teflon® PFA (perfluoroalkoxy), Teflon® PTFE, and Teflon® FEP (fluorinated ethylene polypropylene)) have been evaluated for their ability to transport VOCs in the gas phase. The results indicate that stainless steel is superior to nickel, aluminum, and the polymeric tubings. Polymeric tubings contain varying levels of organic contamination and the outgassing of these contaminants increases when the material is heated. In addition, the transfer efficiencies of the VOCs through polymeric tubing decrease as the aqueous solubility of the analyte decreases. The analytes partition into the polymer and can be recovered; however, volumes of purge gas that greatly exceed the interior volume of the tubing are necessary to recover the VOCs completely and to minimize sample carryover. Additional
purging of the transfer line will decrease the speed of sample collection and complicate the preconcentration of VOCs at the surface by on-line analytical techniques. Metal tubing apparently contains active sorption sites that are efficiently deactivated by water molecules. Transfer efficiencies for VOCs through stainless-steel tubings are nearly 100% in moist gas streams; however, aluminum and nickel tubing retain some VOCs under these conditions. Silcosteel® tubing (Supelco, Bellefonte, PA, USA), a type of glass-lined stainless-steel tubing, may be a suitable material for a cone penetrometer transfer line because of the inertness such tubing has exhibited in laboratory applications and because of its flexibility. Silcosteel® tubing is now used in a transfer line for SVOCs, but the flexibility and ruggedness of tubings having ODs of 0.159 and 0.318 cm have to be evaluated. Passivated metal tubing may be suitable as a transfer line material if it can be produced with a wider ID than a capillary column so that the gas flows that are needed for rapid transfer of analytes can be accommodated.

Parker Hannifin Corp. produces a commercially available heated transfer line (Temptrace®, Parflex Division, Ravenna, OH, USA). Heat-traced lengths of type 316 stainless-steel tubing (0.318 cm OD) have been used in cone penetrometer applications. The tubing has a 24 W ft⁻¹, 120 V, braided constant-wattage heater and aluminum heat-transfer tape that allow the tubing to be heated to 150 °C. The product contains nonhygroscopic fiberglass insulation and a Mylar® moisture barrier and has a urethane jacket. The nominal OD of the heat-traced tubing is about 1.27 cm, which makes it narrow enough to fit within the cone penetrometer rods (2.54 cm ID) that are most commonly used.

ARA developed a unique heated transfer line by using a self-regulating parallel resistance heat trace that is located immediately next to Teflon® PFA tubing. The temperature of the heat trace is monitored by a thermistor located midway along the line. The heat trace and the sample transfer line are encased in a braided fiberglass insulator to prevent heating of the purge gas line and to reduce the temperature so that the line can be handled by the cone penetrometer operator. The heated portions of the line can connect with a second Teflon® PFA tube for supplying the purge gas and electrical leads. The wires and tubes are packaged in a protective plastic tubing to prevent excessive wear and tangling. The line can be heated to 150 °C.

A unique transfer line has been developed that can be heated to 280 °C for the efficient transfer of SVOCs, particularly PAHs, PCBs, and organochlorine pesticides. The transfer line uses Silcosteel® tubing (0.159 cm OD) and is heavily insulated so that it can be safely handled. The tubing is held within high-temperature sleeving and is coated with aluminum foil glass cloth. The tubing is insulated and supported by a bundle of Teflon® tubing. The outer jacket is made with tape and silicone adhesive.

5 CHEMICAL DETECTION TECHNIQUES

A variety of chemical detection technologies have been used to measure subsurface contaminants. These technologies include sensors to provide in situ chemical detection and instrumentation such as gas chromatographs and mass spectrometers that are used in on-line analytical techniques with the cone penetrometer.

5.1 Chemical Sensors

A chemical sensor is a transducer consisting of a physical layer and a chemically selective layer that is capable of providing direct information about the chemical composition of its environment. Chemical detection can be based on the mass of the analyte or its optical, electrochemical, or radiochemical properties.

5.1.1 Mass Sensors

Piezoelectric crystals are sensitive to mass and lack chemical specificity; however, they have been developed as chemical vapor monitors by applying a nonvolatile coating to the crystal that selectively interacts with chemical substances. Several reviews are available on the application of these devices for the measurement of organic vapors. In general, the devices lack specificity for individual chemicals, but arrays of detectors coated with different materials have been used with some success to obtain molecular information; however, detection is typically by chemical compound class.

A portable acoustic wave sensor (PAWS) system has been developed for the real-time analysis of soil gas samples in the field and in situ monitoring of contaminants in vadose-zone monitoring wells. The system consists of a pump to facilitate gas flow across the sensor, a Nafton® dryer to eliminate water from the gas stream, and a three-way valve. The piezoelectric crystal is coated with polyisobutylene. The instrument was evaluated in the laboratory for its ability to quantify TCE and was found to have a detection limit of 8 ppmv, with a dynamic range of 55 000 ppmv. The response was reversible with a 1-s recovery time. Minimum detection limits of 1–10 ppmv were established for many VOCs and were reduced to 10–100 ppbv with a preconcentrator. The system was evaluated in the field in monitoring wells containing tetrachloromethane (CCl₄). At levels of 100–20 000 ppmv, the results were within 2% of those determined with a photoacoustic infrared (IR) system.
The detection limit for CCl₄ was 10 ppmv. Calibrations were stable and were within 1.5% before and after the field measurements. The system has not been adapted for use in the cone penetrometer.

5.1.2 Optical Sensors

Optical sensors are interfaced with the cone penetrometer with fiber optics that are strung through the penetrometer rods to transmit light to and from the sample media. The fiber-optic chemical sensor (FOCS) uses a spectroscopic measurement of the signal. The basic technique of a FOCS can involve (1) a direct spectroscopic measurement of the analyte, (2) reversible binding of the analyte with indicator molecules, or (3) chemical and biochemical reactions of the analyte.

5.1.2.1 Direct Spectroscopic Measurement

Laser-induced Fluorescence Sensor. The first fiber-optic spectroscopic sensor for in situ detection of chemical contaminants by using cone penetrometers was based on measuring the fluorescence of POLs when excited by pulsed ultraviolet (UV) laser energy. That first sensor was developed for SCAPS by the WES and was adapted from a sensor designed by the United States Navy’s Naval Command, Control, and Ocean Surveillance Center; Research, Development, Test and Evaluation Division (NRaD), for seaborne applications. The first-generation SCAPS LIF sensor, shown in Figure 8(a) and (b), consists of a probe with dual fibers for excitation and emission, and a flush-mounted 6.35-mm diameter sapphire window for transmitting the laser illumination to the outside of the penetrometer probe. The UV energy source for this system consists of a pulsed nitrogen laser with an output of 1.4 mJ, 0.8-ns pulse width, 10-Hz repetition rate, at 337 nm. This excitation source represented a mature, commercially available technology that could be readily incorporated into a field LIF system at the time that this effort was initiated in 1989. Another advantage of the 337-nm excitation source, identified at that time, was that fiber attenuation of energy at this wavelength is relatively modest, permitting transmission of the excitation energy over fiber lengths of 100 m or more. This permits the LIF sensor system to be used to the full push capability of the standard 20-ton penetrometer system (i.e. 50 m).

The system uses a spectrograph coupled to an intensified photodiode array and optical multichannel analyzer (OMA) detection system. Because this system uses a diffraction grating to disperse the fluorescence emission signal over a 1024-element diode-array detector, reading out an entire spectral signature from the fluorescing fingerprint signal is possible with a resolution of 0.5 nm or better in approximately 16 ms. In practice, the system usually integrates the emission from 10–20 laser shots, which requires a total analysis time of 1–2 s to collect a fluorescence emission spectral signature. In addition to the optical sensors, the probe also incorporates geophysical sensors that provide continuous soil classification and stratigraphy during the penetrometer push. The LIF probe is also equipped with a grouting system that is used to seal the hole as the probe is being retracted, in order to prevent migration of contaminants across soil layers.
When advanced at the 2 cm s\(^{-1}\) standard push rate, the LIF probe collects contaminant information and soil classification data with a spatial resolution of 2 cm. Figure 9 presents an example of the data that are collected by the SCAPS LIF probe. These plots, which are displayed in real time during the penetrometer push, show the geophysical sensor information that is used to compute the chart of soil classification vs depth, and also a summary of the LIF data (fluorescence intensity and wavelength at peak vs depth). This particular penetrometer push indicates an area of significant POL contamination in a layer 4.2–4.4 m below the ground surface. In addition to the data displayed in Figure 9, the SCAPS data acquisition system collects and stores the complete fluorescence spectrum (1024 points from 270 to 800 nm) for each laser pulse (or average of pulses). After a representative number of penetrometer pushes, the geophysical and fluorescence data are used to develop a model of the subsurface contaminant plume, as shown in Figure 10. The first-generation SCAPS LIF probe was demonstrated in the field in 1990\(^{85}\) and has been extensively used to characterize USDOD and USDOE sites. In addition, this technology has been licensed to private industry, and a number of commercial firms are currently using similar cone penetrometer systems. The SCAPS LIF system has undergone extensive field tests and demonstrations at a number of sites and has proven to be an effective screening tool for mapping subsurface plumes of POL contaminants.\(^{86}\)

A limitation of the 337-nm excitation source identified early in the SCAPS development is that it does not induce fluorescence in single-ring aromatic compounds such as the benzene, toluene, ethylbenzene, and xylene (BTEX) components of fuels. In fact, the lightest weight polycyclic aromatic compound that is excited appears to

![Diagram](image1.png)

**Figure 9** Typical data output of the SCAPS LIF probe at a petroleum-contaminated site. (Courtesy of the US Army Corps of Engineers Waterways Experiment Station.)
be the disubstituted naphthalenes. In general, the 337-nm source is most effective for inducing fluorescence in PAHs with three rings or more. This lack of capability of the nitrogen-based LIF sensor to detect BTEX and light fuels (e.g. the jet fuels JP-4 and JP-5 and unleaded gasoline) has led to a number of efforts to test shorter wavelength sources for incorporation into SCAPS. One of the second-generation SCAPS LIF probes resulting from these efforts is a tunable LIF SCAPS probe currently designated as the Rapid Optical Screening Tool (ROST). The ROST was originally developed for the US Air Force’s Armstrong Laboratory at Tyndall Air Force Base (AFB) by North Dakota State University (NDSU) and is currently produced commercially by Fugro Geosciences, Inc. The system was initially designed as a field-portable LIF sensor to analyze liquid samples containing aromatic hydrocarbons and fuels in monitoring well applications. Subsequently, the sensor was installed in a cone penetrometer probe and was field-tested in a limited number of sites. The system makes use of a frequency-doubled Nd: YAG laser to pump a dye laser the output of which is then frequency-doubled to generate UV light in the range 230–300 nm. In this system, the Nd: YAG laser can also be used directly with harmonic frequency conversion to produce 266-, 355-, and 532-nm outputs. The advantages of these alternative excitation wavelengths include the capability to excite lighter weight aromatic compounds (one- and two-ring aromatic compounds) and to select the most appropriate excitation wavelength for the particular contaminant of interest and the site-specific conditions. One penalty suffered by using shorter wavelength excitation light in the cone penetrometer is that energy losses in the transmission fiber increase dramatically at wavelengths shorter than 290 nm. This loss may preclude effective transmission of short-wavelength light energy over the length of fiber (100 m) required to reach the maximum push depth of a 20-ton penetrometer system. It does appear to be possible, however, to transmit sufficient quantities of short-wavelength light energy over shorter lengths of fiber that could be used to make measurements to depths of 30 m.

Unlike the fixed-wavelength LIF system, the NDSU system uses a monochromator, photomultiplier tube (PMT), and digital storage oscilloscope to detect fluorescence. A major difference in this approach, compared with the OMA detector used by the original SCAPS LIF system, is that in the dynamic or push mode, the detector measures the time decay or lifetime of the fluorescence signal at a single wavelength selected by the monochromator. Full spectral-time decay data matrices can be generated by moving the monochromator in 10-nm increments and recording the time-dependent fluorescence signal at each wavelength. With the present (50-Hz) laser system, this procedure requires approximately 2 min to collect a wavelength–time matrix (WTM) consisting of 21 different wavelengths with a spectral resolution of 10 nm. Another example of a SCAPS LIF probe that incorporates shorter wavelength sources is shown in

![Figure 10 Three-dimensional visualization of LIF probe data, showing underground plume of POLs. (Courtesy of the US Army Corps of Engineers Waterways Experiment Station.)](image-url)
Developed and deployed LIF probes based on adaptations of the initial SCAPS LIF sensor design.

**Laser-induced Breakdown Spectroscopy Sensor.** The laser-induced breakdown spectroscopy (LIBS) sensor is used to detect heavy metals in contaminated soils and groundwater and is based on a simple plasma spectrochemical approach. A high-peak-power laser pulse (typically a Q-switched Nd:YAG laser that produces approximately 10-ns laser pulses with up to 200 mJ pulse energy) is focused on a solid, liquid, or gaseous sample and produces a spark (optical breakdown). The spark emission light consists of unique spectral signatures from excited atoms, radicals, and ions generated from the sample. The plasma emission is collected by optical fibers or lenses and passed through a wavelength dispersive device such as a monochromator or acousto-optical tunable filter (AOTF). The wavelength-resolved light is then detected by a linear diode array, CCD detector, or a single point detector. The information on wavelength and light intensity is passed to a computer, and the data are analyzed by using sophisticated chemometrics software. The output can be used to identify the contaminant and determine its concentration.

The LIBS technique possesses many desirable attributes: (1) compact and lightweight sensors that can be carried by a single person; (2) inherent versatility such that, with the use of optical fibers, any solid, liquid, or vapor sample can be analyzed; (3) no sample preparation; (4) analysis is quick, particularly with the use of high-repetition-rate lasers, array detectors, and high-speed computers; (5) rugged and reliable sensors because all of the electro-optical components are solid-state, and the fiber optics can easily be replaced if necessary; and (6) less-expensive LIBS sensors are possible because of chip lasers and less expensive array detectors.

Figure 12 shows a typical LIBS set-up used in the laboratory for collecting data from liquid and soil samples. An Nd:YAG laser source delivers 80- to 100-mJ pulses at 10 Hz that are focused on an approximately 100-µm spot on the sample. The resulting emissions are collected and analyzed by a spectrometer with an intensified diode-array or CCD detector. Contaminated soil samples are placed on a turntable to expose an undisturbed surface to each laser shot. This arrangement mimics the actual cone penetrometer operation, in which the probe is moving while the laser is firing. An example of LIBS spectra of Yuma sand that has been spiked with various concentrations of Pb salts is shown in Figure 13. The variation in response at a wavelength of about 406 nm is proportional to the Pb concentration. Detection limits ranging from 0.5 to 11 ppm by weight for Pb, Hg, Cr, Cd, and Zn in sand have been achieved with this system.
Research groups at WES and NRaD have field-tested two different cone-penetrometer-based LIBS systems. The first system uses optical fibers to deliver the laser energy (up to 25 mJ at 10 Hz) from the laser in the truck through a sapphire window in the probe to the soil surface. The resulting emissions are collected by a fiber bundle and routed to the spectrometer and computer on the SCAPS truck. The second system, shown in Figure 14(a) and (b), uses a probe-mounted miniature Nd:YAG laser to deliver 80-mJ pulses at 0.33 Hz to the soil surface. The extent of the subsurface Pb contamination found at an Air Force firing range was recently mapped by using the downhole laser LIBS system and is shown in Figure 15.

X-ray Fluorescence Sensor. A cone-penetrometer-based X-ray fluorescence (XRF) system has been developed jointly by the Naval Research Laboratory and WES for detecting metal contaminants in soils and groundwater. The XRF sensors operate by detecting characteristic atomic emissions that result from exciting samples with X-rays. X-rays, which have higher energy than the binding energy of an atomic core electron, will excite core electrons to an empty state above the atomic states. The resulting empty core states are refilled by other electrons within the atom after emitting energy (fluorescing) in the form of lower-energy X-rays. Because the electron energy states producing the fluorescence are entirely within the atom, the X-rays are produced with a constant and well-known energy that is characteristic of individual atomic species. As a result, XRF is sufficiently sensitive to detect many metals at levels of about 10 ppm and does not suffer from matrix effects (where the signal level depends on the exact nature of the chemical bonds involving the target heavy metal and neighboring species) as much as some of the more traditional chemical analytical techniques.
Figure 14 Schematic of a LIBS probe that incorporates a miniature Nd: YAG laser. (a) 1:4 scale including entire laser; (b) 3:4 scale with laser output only. (Courtesy of the US Army Corps of Engineers Waterways Experiment Station.)

Figure 15 Three-dimensional visualization of LIBS probe data showing subsurface lead contamination at a small-arms firing range. (Courtesy of the US Army Corps of Engineers Waterways Experiment Station.)

Implementation of an XRF sensor in the cone penetrometer has been made possible by recent advances in the miniaturization of X-ray source tubes, detectors, and the cooling system required for their operation. Figure 16 shows a schematic of the SCAPS XRF probe, which incorporates a miniature X-ray tube, a boron carbide window to transmit the X-ray excitation and collect the resulting fluorescence, and an energy-dispersive detector. The high-voltage power supply required to operate the X-ray tube is located uphole in the SCAPS truck. The probe has been thoroughly evaluated in the laboratory and has undergone limited field testing.

Ultraviolet Fluorescence Probes. An in situ ultraviolet fluorescence (UVF) probe has been proposed to detect single-ring aromatic compounds in groundwater. Unlike LIF, where the UV radiation is generated by
a laser, the UVF probe uses a mercury vapor lamp as the UV source. Preliminary evaluation of the method with a benchtop version of the probe has been made. A miniaturized lamp and PMT have been proposed for use in a cone penetrometer, which would preclude the use of fiber optics. The volatile aromatic hydrocarbon concentration is estimated from the ratio of the fluorescence of the contaminant–water mixture to the fluorescence of the contaminant–water mixture after it has been purged with an inert gas. Using the ratio of the fluorescence signals is necessary because the method is nonspecific, and fluorescence from humic substances would interfere. These substances are nonvolatile and cannot be purged from water; however, turbidity was found to interfere with the analysis. Therefore, the sample would have to be filtered before the measurement. The detection limit for a laboratory benchtop device was 500 ppb. Lower detection limits are expected for a miniaturized version.

Recently, a patent was awarded for a cone penetrometer UVF probe to detect POL contaminants. In this design, a UV lamp located in the probe housing provides excitation energy, which is reflected through a UV-transparent window in the housing to the soil by one or more reflecting elements in the housing. The reflecting element or elements allow longitudinal offset of the lamp from the window, providing space for a high-intensity UV lamp. Fluorescence emitted from contaminants in the soil is transmitted through the window and collected by a fiber-optic link which, in turn, transmits it to the instrumentation at the surface. A concentrating reflector between the lamp and the housing and a focusing lens between the lamp and the reflecting element collect and focus excitation energy from the lamp. A filter between the lamp and the first reflecting element eliminates unwanted wavelengths from the excitation energy, and a filter between the window and the fiber-optic link removes unwanted wavelengths from the emission spectrum. The design should improve sensitivity, especially for the lighter POL contaminants, and eliminates the need for complicated and expensive laser excitation equipment at the surface.

Fiber-optic Raman Sensors. Raman sensing is a spectroscopic technique that is useful for detecting nonfluorescing chemicals such as solvents and other VOCs. Detection is based on measuring the wavelength shift of monochromatic light scattered from the sample. The measured wavelength shift (i.e. the Raman shift) is characteristic of the molecular structure of the sample. The drawback to this type of sensing is that the Raman signal is approximately six orders of magnitude weaker than the signal produced by LIF. Nevertheless, the Raman technique is suitable for detecting accumulations of chemical contaminants as light nonaqueous-phase liquids (LNAPLS) or dense nonaqueous-phase liquids (DNAPLS), which tend to collect in subsurface pools of almost pure product. The NRaD has developed and field-tested a SCAPS fiber-optic Raman sensor (FORS) probe for detecting pools of VOCs. The FORS system is very similar to the original SCAPS LIF system described previously. The FORS system employs a nitrogen laser coupled to a single delivery fiber and a sapphire window to excite the soil or groundwater outside the probe. In order to maximize the relatively weak Raman signals, seven collection fibers are used, instead of the single fiber used in the LIF probe. Each fiber is equipped with a filter module consisting of two graded index (GRIN) lenses to collimate light from the fiber and filters. The excitation fiber has a band-pass filter module to isolate the excitation laser line from emissions from the fiber. Each collection fiber has a long-pass filter module to reject the laser line while allowing the Raman-shifted signal from the sample to be transmitted. Figure 17(a–e) shows an example of data collected by the FORS system. The spectra shown are those of toluene in a sand matrix. Figure 17(a) shows the Raman lines of toluene superimposed on a fluorescence background, and also Raman emissions from the fibers. Because the fiber background has been well characterized, it can be subtracted, as shown in Figure 17(b). The fluorescence background signal can be eliminated either by taking the derivative of the second spectrum (Figure 17c) or by fast Fourier transform (FFT) filtering (high-pass filtering in the frequency domain), as shown in Figure 17(d). For comparison purposes, a Raman spectrum of neat toluene is shown in Figure 17(e).

To improve the sensitivity of FORS probes, a number of probes have been developed that make use of surface-enhanced Raman scattering (SERS), in which the analyte of interest is deposited on a specially prepared rough metal surface. The effect of SERS is to enhance the Raman signal by up to eight orders of magnitude. The NRaD is currently developing a SCAPS FORS probe equipped with organic-coated SERS substrates for selective detection of BTEX and chlorinated solvents; the detection capability is much improved over the original SCAPS FORS probe.

Fiber-optic Infrared Reflectance Probe. Remote fiber-optic Fourier transform infrared (FTIR) spectroscopy is a direct spectroscopic technique that can be used to detect trace amounts of organic contaminants in subsurface media. A fiber-optic infrared reflectance (FOIR) probe has been developed that illuminates the soil with a broad-band optic source through a sapphire window in the cone penetrometer. The diffuse reflectance from the soil is collected through the window and transmitted through an optical fiber to the surface, where it is spectrally analyzed with an FTIR spectrometer.
FIELD-PORTABLE INSTRUMENTATION

Figure 17 Raman spectra collected with a FORS probe. Parts (a–e) are described in the text. (Courtesy of Naval Command, Control, and Ocean Surveillance Center, Research, Development, Test and Evaluation Division.)

Figure 18 Schematic of a FOIR probe.\textsuperscript{[101]}

(Figure 18). The broad-band optic source is a Nichrome wire representing a blackbody source at a temperature of 1000 K. Arsenic/sulfur-based chalcogenide optical fibers were found to be more rugged and chemically suitable than fluoride-based fibers. The IR diffuse reflectance was measured with a mercury cadmium telluride detector having a wavelength cutoff of 19 μm. The spectral content was obtained with a KVB/Analet FTIR spectrometer with a resolution setting of 4 cm\(^{-1}\). A lithium niobate wafer was placed in front of the detector to filter radiation with wavenumbers below 2225 cm\(^{-1}\). The operating wavenumber range for the system is 6000–2225 cm\(^{-1}\).

The method was tested in the laboratory by spiking sand with levels of TCE from 250 to 1000 ppm.\textsuperscript{[102]} The C–H absorption bands of the chlorinated hydrocarbons occur in the wavenumber region from 3100 to 2850 cm\(^{-1}\). An H–S absorption band at 3200 cm\(^{-1}\) from the chalcogenide fiber was also observed and used as an internal reference to reduce the matrix dependence of the measurement. Laboratory experiments showed that the minimum observable concentration of TCE in sand was approximately 250 ppm. The technique has also been used to measure a mixture of benzene and TCE on sand.\textsuperscript{[100]} Diesel fuel marine (DFM) has also been measured with this technique. The band depth was linearly related to the DFM concentration at levels up to 1 wt%; however, calibrations at higher concentrations required the use of band depth and spectral shape analysis. Increasing the sensitivity of the technique has been proposed by using a relatively narrow-band detector such as indium antimonide and by increasing the optical power delivered to the detector.\textsuperscript{[101]} Better transmission of power may be achieved by (1) using a more powerful optical source, (2) using lower-loss fibers, and (3) improving the collection efficiency at the fiber facet; however, increasing the power may promote vaporization of the analyte and water. The water absorption bands may interfere because of their proximity to the C–H stretch of the hydrocarbons.

5.1.2.2 Indicator Coatings FOCSs\textsuperscript{™} have also been developed in which the analyte binds reversibly to an indicator coating on the fiber. The coating is designed to have a chemistry that is specific to the analyte. The chemistry results in a change of the refractive index of the sample that can be related to the analyte concentration. Optical fibers have also been coated with fluorescent dyes. These techniques have not been interfaced with the cone penetrometer but they have been deployed in monitoring wells. Typical sensitivities for substances in the gas phase are in the range of parts per million by volume (ppmv), with sensitivities as low as 100 ppm for substances in the aqueous phase. FOCSs\textsuperscript{™} have been developed to detect hydrocarbons in leaking underground fuel storage tanks,\textsuperscript{[102]} aromatic hydrocarbons,\textsuperscript{[103,104]} and volatile organohalogen compounds.\textsuperscript{[105]}

5.1.2.3 Chemical Reactions  A FOCS™ system has been interfaced with the cone penetrometer for the in situ detection of TCE in soil gas.106,107 The detection system is based on the Fujiwara reaction, in which an organohalogen reacting with pyridine in basic solution produces a characteristic color change. Sensitivity to various organohalogens is determined by the amount of tetrabutylammonium hydroxide in the reagent and generally increases as the number of chlorine atoms in the molecule increases. The FOCS™ system consists of three components: the reagent, the electro-optical system, and the sensor cell (Figure 19).108 The sensor cell is a flexible tube of semipermeable material that is connected at both ends by stainless-steel capillaries. One capillary contains the input optical fiber originating from the source lamp and the reagent fill tube, and the other capillary contains the output optical fiber to the detector and reagent drain tube. Organohalogens are transferred through the membrane and react to produce a color change. The intensity of the color change is dependent on the concentration of the analyte and is monitored with optical fibers. The pumping system consists of a computer-controlled syringe pump and six-way valve for transferring the chemical reagent. The sensing reaction is irreversible; however, the solvent-delivery system has the capacity to make 60 measurements. The optical system consists of a portable fluorimeter that includes a source lamp, fiber optics to carry the probe and modulated beam to and from the sensor cell, a filter, and a silicon photodiode that uses a phase-sensitive, differential-absorption detection technique. The sensitivity of the device for TCE is about 200 ppbv, with an upper limit of >500 ppmv. The system has also been commercialized (PurSense™ THM-1; Purus, Inc., San Jose, CA, USA) for the detection of both TCE and trihalomethanes in water and air.109 The commercialized sensor is linear up to 1 mg L⁻¹. Detection limits for analytes in the gas phase are about 100 ppbv. The operating cycle of the trace analysis is 60 s for reagent flushing and 90 s for measurement. The chemistry is selective, and interferences from polar aqueous-phase analytes containing both halogens and oxygen atoms are low because of the high aqueous solubilities of these substances. The system is more selective when used in the headspace mode than it is when used in the determination of halogens in the aqueous phase directly. Direct detection in the aqueous phase is complicated by fouling of the membrane with inorganic salts, nonvolatile organic compounds, and microorganisms.

The WES has developed a cone penetrometer probe that uses chemically treated tapes that are exposed to the environment outside of the probe to detect the presence of explosive contaminants. When the tape comes into contact with 2,4,6-trinitrotoluene (TNT), a reaction causes the tape to change color, which is detected via a fiber by a spectrophotometer mounted on the cone penetrometer truck.110 The tape is continuously fed during the penetrometer push from a slot near the tip.
and passes over a sapphire window where color changes are transmitted by the fiber-optic link. Some of the shortcomings of the colorimetric method include rather poor sensitivity and a tendency for the tape to break during the push.

5.1.3 Electrochemical Sensors

Electrochemical sensors have many properties that make them attractive for in situ applications in the cone penetrometer, including (1) small size, (2) simple circuit requirements, (3) no chemical waste, (4) low power requirements, and (5) powerful analytical properties, including high sensitivity, modest selectivity, and a fully reversible response. A thorough discussion on the design and mechanism of operation of electrochemical gas sensors operating in the amperometric mode has been presented. For proper amperometric operation of these sensors, the analyte must be electrochemically active and must come into actual physical contact with the active electrode of the sensor. For the electrochemical sensing of gases, the added requirement is that the analyte be in the vapor phase. Amperometric instrumentation and methods have been developed for the selective detection of several important environmental contaminants. The WES and Transducer Research Inc. (TRI) have developed a number of SCAPS probes equipped with electrochemical sensors for detecting explosives, chlorinated solvents, and VOCs.

The traditional methods to measure TNT and other explosives in environmental samples include sample collection, preparation, and sophisticated laboratory analytical procedures. Field-assay kits are available; however, the sample must be collected and prepared for analysis with chemical reagents that require disposal. Recently, an analytical method for the measurement and quantitation of soil-bound TNT and other explosive contamination has been developed that uses electrochemical sensors operating in the amperometric mode. Gas sensors cannot measure TNT directly because of its low vapor pressure. Therefore, it was necessary to develop a method that increases the vapor pressure of TNT or appropriate signature compounds. The thermal analysis of nearly all organic compounds over heated noble metal surfaces in air generates electrochemically active vapors. The distribution of thermal products depends primarily on the temperature and nature of the catalytic surface, which can be precisely controlled, and the compound undergoing pyrolysis. The thermal decomposition of TNT, hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX), octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX), and other explosives over heated noble metal surfaces generates characteristic products that can be efficiently detected by electrochemical gas sensors. The signature vapors generated by thermal catalysis of a number of different explosives have similar characteristics. TNT, RDX, and most other explosives contain nitro (NO₂) groups, and the catalytic degradation of explosives not only generates carbon dioxide, carbon monoxide, and water, but also nitrogen- and oxygen-containing compounds according to Equation (1):

\[
C_7H_5(NO_2)_3 + O_2 \rightarrow CO_2 + H_2O + CO + NO, NO_2, HONO, etc.
\]

Several of these thermal decomposition products are readily detectable with electrochemical sensors. A SCAPS explosives probe that incorporates electrochemical sensors for the in situ measurement of explosive contamination and geophysical sensors for determining soil layering has been jointly developed by the WES and TRI. The probe collects information on soil classification during the penetrometer push and collects contaminant information during penetrometer retraction. Figure 20 illustrates the main components of the

![Figure 20](image-url)
SCAPS explosives probe. The probe incorporates an external pyrolyzer system that transforms explosive compounds into electroactive vapors (NO, NO₂, and CO). A pneumatic system transports the pyrolyzed vapors from the soil to the electrochemical sensors inside the probe that generate electrical signals proportional to the concentration of the electroactive vapors. The probe’s umbilical (1) allows the chemical sensor signal to be monitored continuously at the surface, (2) ensures positive flow of clean air through the vapor sampler, (3) supplies power to the pyrolyzer during analysis, (4) interfaces the geophysical sensors to onboard SCAPS computers providing real-time soil classification data, and (5) supplies grouting fluids to the tip of the probe. A sacrificial sleeve is used to protect the vapor-sampling ports and the pyrolyzer unit during the penetrometer push. The sleeve is removed during retrieval by soil friction, thereby exposing both the pyrolyzer and the air/vapor sampler system. Laboratory tests have demonstrated sensitivities of better than 1 ppm by weight for TNT in sand.¹¹⁷

A probe similar to that used for explosives detection has been developed by the WES and TRI for the detection of VOCs in the vadose zone [RCI probe¹¹⁶]. The probe is equipped with electrochemical sensors that detect general classes of VOCs and some halogen-containing compounds (with no known interferents). The probe does not require an external heater because the analytes of interest are present in the vapor phase.

A novel solid-state electrochemical diode detector has been developed for the selective detection of halogenated VOCs and a metal-oxide semiconductor (MOS) gas sensor for the detection of aliphatic and aromatic hydrocarbons and common oxygenated hydrocarbons such as alcohols and ketones in the vadose zone or in the headspace of groundwater.¹¹⁸ The solid-state electrochemical diode detector consists of a tiny bead of a high-temperature solid-state electrolyte deposited on a noble metal filament. A current is passed through the bead to heat it to several hundred degrees Celsius. Halogenated organic compounds in the soil decompose, releasing halogen ions that are transported through the bead and cause a measurable increase in conductivity. The response is nonlinear and must be calibrated at several concentrations. The MOS sensor consists of a ceramic tube coated with tin oxide that is heated with a filament to several hundred degrees Celsius. The detector exhibits some selectivity to aliphatic and aromatic hydrocarbons and common oxygenated solvents such as alcohols and ketones. The MOS sensor does not respond to fully chlorinated compounds such as CCl₄ and responds weakly to many other chlorinated hydrocarbons. The sensitivity of the solid-state electrochemical diode detector for CCl₄ is about 2 ppbv and that of the MOS sensor for benzene is about 200 ppbv.

5.1.4 Radiochemical Sensors

The WES, in collaboration with the USDOE, developed a SCAPS spectral γ-probe for passive detection of radioactive wastes.¹¹⁹ The probe, shown in Figure 21, consists of a detector crystal that is optically coupled to a PMT, power supply, microprocessor, and high-voltage supply. When a γ-ray from radioactive sources in the soil strikes the crystal, it emits a photon, which is detected by the PMT and converted into an electrical voltage. The amplitude of this voltage is proportional to the energy of the photon, which, in turn, is proportional to the energy of the incident γ-radiation. This analog signal passes through a high-speed analog-to-digital converter (ADC) and is digitized. From the ADC, the resulting value is passed on to a microprocessor, which sorts the value within a histogram of counts versus energy. Characteristic peaks in the γ-spectrum indicate the presence of emitting radionuclides. The probe samples 512 channels of γ-radiation in the energy range 100 keV–3 MeV at a rate of one complete spectrum every 2 s. The detector is controlled by an onboard microprocessor, which transmits the digital values along a four-conductor logging cable to a microcomputer for storage and display. The detector offers a choice of three different 1 × 3 in crystal types: NaI, CsI, and bismuth-germanium-oxide (BGO); however, NaI currently appears to be the only one of the three with sufficient resolution for high-performance spectral analysis. In addition to the γ-sensor, the SCAPS probe is also equipped with geophysical sensors to provide real-time soil classification.

This probe was initially field-tested at the USDOE’s Fernald Site near Cincinnati, Ohio, in September 1994. First, the probe was lowered into test drums that had been prepared with known amounts of U-238. The drums were tested for 30 min each. Real-time software developed by Pacific Northwest National Laboratory (PNNL) identified suspected contaminants and their concentrations. Next the SCAPS truck was moved to a contaminated field location, where several pushes were made at predetermined locations. Operators could view soil classification and gross γ-counts versus depth during the push. The probe was also parked at selected depths for a more detailed spectral investigation.

After the first-generation spectral γ-probe had been field-tested, certain improvements and modifications to the probe were identified, and a second-generation spectral γ-probe was fabricated, which has higher resolution and is less expensive than the first-generation probe. The resolution of the NaI detectors (about 14%) was not sufficient to observe some spectral peaks of interest. The required probe sensitivity is such that it would be capable of locating and identifying U-238 in concentrations as low as 35 pCi g⁻¹ in soil. The first-generation probe
had a lower limit of detection for U-238 of between 60 and 80 pCi g⁻¹. The improved probe incorporates NaI detectors with a resolution of better than 9%, a higher resolution PMT, and better optical coupling between the crystal and PMT. In addition, the first-generation probe had a considerable redundancy of costly electronics, because each probe contained an ADC, high-voltage supply, power supply, and microprocessor section. To reduce the cost and redundancy of the improved probe, all of the electronics, with the exception of the detector and preamplifier, were relocated into the SCAPS truck. Thus, each probe can share a common high-voltage supply, power supply, ADC, and microprocessor section. This design allows the operators to adjust gain levels from an amplifier located in the SCAPS truck, rather than inside the probe, and reduces the cost of the technique because the downhole equipment could be lost in the event of a rod failure.
5.2 Gas Chromatography

A GC system consists of an injection system, an analytical column, and a detector. The smallest field-portable instruments, with the exception of the Cone-GC™, have not been miniaturized for incorporation into the cone penetrometer; however, field-portable and transportable gas chromatographs have been used to analyze samples collected from the subsurface and have been interfaced with cone penetrometer isolation devices. Injection systems typically include a module for analyte preconcentration and water management. Capillary columns allow the complete resolution of complex mixtures in about 30 min. Detectors typically include electrolytic conductivity, electron-capture, flame ionization, photoionization, and thermal conductivity types. Sensitivities of these detectors range from 10 ppt to 1 ppm. Comparison of the retention times of analytes and standard materials under identical chromatographic conditions provides a tentative identification of the contaminant; however, a more positive identification can be made by analyzing the sample on columns of widely different polarities. Detector specificity also permits some tentative identifications to be made. Consequently, GC systems that have multicolumn and multidetector capabilities are very useful in subsurface contaminant applications.

ARA has proposed interfacing the CISP™ and DTD™ probes with a high-speed GC system to measure subsurface fuel contamination. High-speed GC techniques are being developed for the rapid screening of gasoline-to-diesel-range organic compounds in soils and soil gas. In a high-speed screening mode, BTEX can be detected in 10–20 s, with sensitivities in the parts per billion range, by using a photoionization detector. In a high-resolution advanced field analysis mode, fingerprint chromatograms are obtained to determine fuel type in about 200 s with a flame ionization detector. The advantage of using high-speed GC over conventional chromatography is that analysis times can be reduced from 30 min to about 100 s. For example, by combining high-speed column switching and pressure-adjustable selectivity, a complete separation of 20–30 VOCs has been accomplished in <1 min. The technique relies on the injection of a very small gas plug from a cryointegration inlet. Sample injections are typically limited to about 2 mL of water-saturated air. Further work on injection systems needs to be done to apply the method to subsurface analysis.

A GC system has been developed that can fit within a cone penetrometer (Cone-GC™) to monitor solvents selectively in the vadose zone or in the headspace of groundwater (Figure 22). The system has a 2.5 cm OD by 91 cm long GC probe assembly that can fit inside a conventional cone penetrometer, a 30 m long connecting cable assembly, and a power/data acquisition assembly that allows user interaction with the GC probe. An automated valving system is used to collect the sample in either a 0.33-mL loop or a sorbent tube and complete the injection into the gas chromatograph. The analytical column is a 0.159 cm OD packed column that is 91 cm long. A novel solid-state electrochemical diode detector is used for the selective detection of halogenated solvents, and a MOS gas sensor is used for the detection of aliphatic and aromatic hydrocarbons and common oxygenated hydrocarbons such as alcohols and ketones. Typical analysis times are <10 min; however, the fast analysis times of the Cone-GC™ are limited by the low chromatographic resolution and may not be suitable to resolve complex mixtures of contaminants.

5.3 Mass Spectrometry

MS has been used extensively to monitor subsurface contamination because of its ability to quantify organic compounds accurately and simultaneously to provide positive identification of the analytes. Field-portable and transportable systems can be installed in complex mixtures of contaminants.

Figure 22 Diagram of the Cone-GC™ probe system, developed by Microsensor Systems, Inc. (Bowling Green, KY, USA).
the cone penetrometer truck for ease of analysis in the field. Mass spectrometer systems have been directly interfaced to sampling devices in the cone penetrometer and also used in the field for the analysis of samples collected by conventional sampling devices in the cone penetrometer. The mass analyzers that are most commonly used in field instruments are the linear quadrupole and the quadrupole ion trap. The linear quadrupole has moderate to low resolution capability. The ion trap is 10–100 times more sensitive than the linear quadrupole; however, the instrument may suffer from considerable drifts in the mass spectra.

Direct-sampling ion-trap mass spectrometry (DSITMS) has been developed to provide faster and less costly methods for the analysis of organic contaminants in environmental samples. The analytes can be introduced directly into the mass spectrometer with no sample preconcentration and little or no sample preparation. The analytes are monitored in real time or near real time at low parts per billion levels. Analysis times range from instantaneous to approximately 3 min. Several sample introduction systems have been developed for the DSITMS system that include a soil/water purge module, a TD module for sorbent tubes, and a direct air-sampling module for real-time monitoring of VOCs. Detection limits for VOCs in water and soils are about 1–5 and 10–30 ppb, respectively. Air samples can be quantified down to 1 ppb. Sample preconcentration can extend the detection limits down to 50–100 pg. The system has been used to analyze sorbent tubes from the TDS™ and has the potential to be interfaced with some of the cone penetrometer isolation devices to provide an on-line analytical capability. For example, DSITMS has been interfaced with the Hydrosparge™ for the rapid analysis of groundwater by using the cone penetrometer.

A field-transportable TD mass spectrometer has been used to characterize PCBs, PAHs, and VOCs in subsurface samples. Analysis of VOCs in groundwater, PCBs in soil, and PAHs in soil required about 10, 10–15, and 20–30 min per sample, respectively, using a short GC column sampling probe as a fast GC system. Interfacing the TD mass spectrometer with the TECP™ has significantly reduced the analysis times. Analysis times are approximately 7 min per sample for SVOCs and VOCs using ion fingerprint detection algorithms. Detection limits are in the parts per million range for soil.

6 TECHNOLOGY DEMONSTRATION AND VALIDATION

As with any new technology, before the novel techniques described in this article can gain widespread acceptance and begin to replace conventional methods, the following questions must be addressed:

1. Are there significant and quantifiable improvements in the speed, cost, sensitivity, and accuracy of the technique over conventional methods?
2. What is the quality of the data in widely varying soil and groundwater types?
3. How rugged, operable, and user friendly are the technologies under actual field conditions?
4. Will the innovative methods be accepted by the appropriate regulatory agencies?

A large number of technology demonstrations have been and are currently being conducted to transfer the innovative cone penetrometer technologies from the laboratory development and testing phases to their implementation in the field. For example, the USDOE began the Rapid Commercialization Initiative (RCI) to assist inventors of environmental technologies, including cone penetrometer devices, in bringing their devices to the commercialization phase. The RCI assists the private sector and state and federal agencies in (1) finding appropriate sites for the demonstration and testing of mature environmental technologies, (2) verifying the performance and cost of the technologies, and (3) facilitating and expediting the issuing of permits. The following discussion contains a brief synopsis of several field demonstrations and validations of cone penetrometer chemical technologies. The data from these demonstrations were made available to the authors but do not include the entirety of the data available from field demonstrations of cone penetrometer devices. Other devices that were described in sections 3, 4, and 5 are also in the laboratory and field validation phases, and the reader is encouraged to contact the investigators directly for additional information on their validation, regulatory acceptance, and commercialization.

6.1 Samplers

The cone penetrometer samplers are designed to perform an in situ collection of groundwater, soil, and soil gas. Following sample collection, the probe is usually brought to the surface, and the sample is transferred to a container and analyzed on-site or transported off-site to a laboratory for analysis. Comparisons between groundwater samples collected by the BAT™ and HydroPunch™ devices with samples collected from nearby monitoring wells by using bailers have usually been favorable. The groundwater that is isolated in monitoring wells represents a wider subsurface strata than the narrow depth sampled by the in situ devices; therefore, some discrepancies are expected. The sealed container of the BAT™ sampler and the pressurized chamber of the
Implant systems that contain permeable Teflon used to validate the soil gas probes. They are soil gas cone-sippers of aromatic and chlorinated aromatic hydrocarbons to preserve the integrity of the sample, particularly transferring the samples to containers before analysis. Attention must be paid to subsampling the soil cores and accommodate the electronic cone, and its adaptability to an on-line analytical technique.

Soil coring devices operate effectively; however, careful attention must be paid to subsampling the soil cores and transferring the samples to containers before analysis to preserve the integrity of the sample, particularly for VOCs. Significant losses of VOCs have been observed when subsamples were transferred by spoon to glass vials. Soil residues retained on the threads of the vials prevented the caps from sealing properly and permitted VOCs to volatilize from the sample container. Quantitative results for VOCs were obtained by using open-barrel plastic syringes to subsample the soil core and to transfer the sample to a glass vial.

The comparability of the soil gas concentrations determined by soil gas probes to the actual soil gas concentrations are unknown. VOCs are suspected of being volatilized from soil by the vacuum that is applied to transfer the soil gas sample through a transfer line to a container or gas analyzer at the surface. Consequently, the soil gas concentrations may be dependent on the ability of the soil to supply gas at a rate comparable to the rate at which it is withdrawn to the surface. Direct comparisons with soil gas concentrations determined with, for example, the passive dual planar membrane organics monitor (PDPMOM) or its predecessor, the TerraTrog™ system could possibly be used to validate the soil gas probes. They are soil gas implant systems that contain permeable Teflon® or polyimide membranes through which the soil gas enters a sample chamber. An inert gas is used to purge the sample chamber and transfer the soil gas to the surface. Soil gas enters the chamber because of the difference in partial pressure of the analyte in the soil gas and the inert purge gas. This collection method is more passive than the soil gas probes even when it is used in its dynamic purging mode because it does not reduce the pressure at the particle surface. Soil gas probes can be used as effective screening tools for site characterizations when used in concert with analyses of groundwater and soil at the site.

### 6.2 On-line Analytical Techniques

Cone penetrometers that incorporate in situ isolation techniques to purge VOCs from groundwater were developed to eliminate the transfer of groundwater from the in situ sampling probes to a container prior to chemical analysis and to minimize losses of analytes (section 4.1). The groundwater probes include the ISPD™, the CISP™ probe, and the Hydrosparge™. The ISPD™ and the CISP™ probe have been tested in the laboratory and have undergone preliminary field tests; however, further testing of these devices is necessary. Field tests of the ISPD™ and the CISP™ probe have revealed that the design of the sample inlet is critical to the successful operation of these purge devices. The purging of water to quantitatively recover VOCs is an accepted methodology; however, the use of this technique in a groundwater probe is complicated by the necessity to filter the water as it enters the probe. The filter of the ISPD™ has a tendency to clog. The CISP™ probe incorporates a two-stage filter that has worked more effectively. The Hydrosparge™ is deployed within the HydroPunch™ and PowerPunch™ samplers. The water inlets of these samplers are filters with large surface areas that facilitate the collection of groundwater; however, the HydroPunch™ and PowerPunch™ samplers cannot incorporate the electronic cone and do not have the multiple-depth-sampling capabilities of the ISPD™ and CISP™ probe.

The Hydrosparge™ has been undergoing extensive technology demonstrations since 1996 to obtain regulatory acceptance. The initial field demonstrations were funded by the Environmental Security Technology Certification Program (ESTCP) and were conducted at Aberdeen Proving Ground (APG), Maryland, during June 1996 and near the McClellan AFB Annex, Davis, California, during November and December 1996. During these demonstrations, the Hydrosparge™ results were validated against groundwater samples that were bailed from the HydroPunch™ wells after the Hydrosparge™ data had been collected. Laboratory analysis of the bailed samples was conducted by USEPA Method 8260A, while samples from the Hydrosparge™ were analyzed by an on-line analytic technique in the field using a Teledyne™ DSITMS. Figure 23 shows the Hydrosparge™ measurements of tetrachloroethene (PCE), TCE, and dichloroethene (DCE) plotted against the results from the laboratory analyses of the samples that were bailed from the HydroPunch™. The plot indicates a high degree of agreement between the in situ purging technique and the conventional method of bailing a sample from a groundwater sampler, transferring the sample to a container, and analyzing the sample in the laboratory. Table 1 summarizes some of the results from the field demonstration.
The Hydrosparge™ demonstrations at APG also yielded valuable cost comparisons between the two techniques. Using conventional site characterization cost and time estimates provided by the APG site manager and actual SCAPS cost data, it is estimated that a SCAPS investigation using the Hydrosparge™ probe saved over $300,000 and was completed in approximately 15% of the time that conventional methods would have required.

Cone penetrometer devices that incorporate in situ isolation techniques to thermally desorb VOCs from soil were developed to perform an in situ analysis of the VOCs and SVOCs in soil and eliminate the collection of soil cores and the analysis of subsamples in the laboratory. The devices include the TDS™, the DTD™ probe, and the TECP™. Of the three probes, the TDS™ has undergone the most extensive field testing. Recoveries of analytes by each of these probes are directly correlated with the moisture content of the soil and are related to their ability to dry the soil during the TD step. Recoveries generally decrease with increasing soil moisture. A distinct advantage of the TDS™ over the other devices is its ability to desorb thermally a known volume of soil; however, the mass of the soil sample is still unknown.

Results obtained with the TDS™ were validated by collecting soil samples adjacent to the TDS™ sampling locations with a cone-penetrator-deployed split-spoon sampler. A subsample of soil from the split-spoon sampler was extracted, immediately placed in methanol in accordance with the method of Hewitt, and analyzed by an off-site laboratory using USEPA Method 8260A. Another subsample was placed directly in the probe, thermally desorbed, and analyzed onboard the SCAPS truck with a DSITMS. The TDS™ measured 21 discrete samples during eight pushes (Table 2). The maximum

sampling depth and distance to the water table were 11 and 10 m, respectively, below the ground surface. PCE was the primary volatile contaminant detected by the TDS. PCE was found at levels below the detection limit in a few samples; however, only one sample analyzed by the off-site laboratory indicated the presence of TCE in the soil. Concentrations of PCE were generally low, ranging from undetectable to 100 ng g\(^{-1}\) in both the TDS samples and the verification samples collected with the split-spoon sampler (Table 2). Concentrations of VOCs in many of the soil verification samples were less than the lower reporting limit for USEPA Method 8260A and are, therefore, reported as estimated (\(L\)) values. In general, results from subsamples of soil from the split-spoon sampler that were thermally desorbed and analyzed with the DSITMS are within a factor of two of the subsamples analyzed by USEPA Method 8260A.

6.3 Chemical Detection Techniques

Chemical sensors have been interfaced with the cone penetrometer to perform an in situ analysis of the subsurface media. The analyte isolation and transfer steps are eliminated, and thus these techniques provide a rapid analysis of the subsurface media. The SCAPS LIF sensors represent the first and most mature cone penetrometer chemical detection technology. The LIF sensor has undergone extensive field testing, demonstration, and validation since 1991 and has received regulatory acceptance, has been licensed and commercialized, and is being routinely used in site characterization and remediation operations. By the end of 1996, the US Government-owned SCAPS units equipped with LIF sensors had already completed over 200 site investigations. The SCAPS LIF demonstration and validation project and its approach to obtaining regulatory acceptance have become the model for other cone-penetrometer-based site characterization technologies.

During August 1994, the USEPA conducted an evaluation of the SCAPS LIF sensors (both the nitrogen laser and the tunable-laser-based systems) at three POL-contaminated sites as part of the Superfund Innovative Technology Evaluation Program. The USEPA evaluated the SCAPS operating procedures, costs, and data quality and compared them with the most appropriate conventional method of drilling, sampling, and laboratory analysis. After the conclusion of the three field evaluations, the USEPA published an innovative technology evaluation report,\(^\text{86}\) which concluded that the SCAPS technique using the LIF sensor generated screening-level data faster than the conventional methods and with little or no generation of waste. The SCAPS operation also required less manpower than conventional methods, was less expensive ($20,000 to characterize all of the three sites, compared with $43,000 for drilling and sampling), generated almost 1200 more data points than the conventional approach, and provided both contaminant and stratigraphic data in real time. One identified drawback of the SCAPS technology was the need for laboratory analysis of critical samples because the SCAPS LIF sensors provided screening-level data rather than definitive quantitative data. Detection thresholds for the SCAPS LIF technologies are estimated in the innovative technology evaluation report to be 60 mg kg\(^{-1}\) for total petroleum hydrocarbons and 19 mg kg\(^{-1}\) for volatile petroleum hydrocarbons. The USDOE\(^\text{138}\) and the Naval Facilities Engineering Command\(^\text{139}\) evaluated the SCAPS LIF technology and estimated costs that were up to 50% lower than site characterizations using conventional methods. The SCAPS LIF sensor program has actively pursued regulatory acceptance by conducting extensive field demonstrations, together with laboratory verifications for numerous Federal, state, and local regulatory agencies. The NRAD in San Diego, California, has been very active in pursuing regulatory acceptance for the SCAPS LIF through a series of well-designed and publicized demonstrations that have involved representatives from the USEPA, the California Environmental Protection Agency, the Western Governors Association, and the Interstate Technology Regulatory Cooperative. Demonstrations of the SCAPS that included extensive verification sampling were conducted at the Hydrocarbon National Test Site located in Port Hueneme, California, and at arid sites at Sandia National Laboratories in New Mexico during 1995. The results of these demonstrations culminated with the SCAPS LIF technology being first certified in 1996 by the California Environmental Protection Agency, followed thereafter by multistate certification, and recognition as a screening-level tool by the USEPA.\(^\text{86}\)

Another SCAPS technology that recently transitioned to the ESTCP field demonstration and validation program is the electrochemical sensor probe for detecting explosives in soils. Initial field evaluations at the Louisiana Army Ammunition Plant (LAAP), the Volunteer Army Ammunition Plant (VAAP) in Tennessee, the USDOE’s Pantex facility in Amarillo, Texas, and the Longhorn Army Ammunition Plant (LHAAP) in Texas demonstrated the sensor’s capability to detect low (parts per million) to moderate (10%) levels of explosives (TNT, RDX, and HMX). Table 3 shows a qualitative comparison of the sensor results with those from soil samples that were analyzed using USEPA Method 8330 to validate the results. This contingency analysis involves evaluation of the frequency of the sensor’s true positive and negative response as determined by results from the validation sample. A true-positive sensor response is assigned whenever the validation sample indicates the presence of an
explosive contaminant at a location where the sensor yields a response above background. Similarly, a true-negative response is assigned where both the validation sample and the explosive sensor yield no response above background. A compilation of data from the field tests indicates that the explosives sensor yielded 87 and 75% true-positive and true-negative responses, respectively (Table 3). The false-positive responses observed may be due to the presence of nonexplosive nitrogen species present in the soils or may be attributed to inhomogeneity of TNT in environmental samples. Additional electrochemical sensors have been incorporated into the SCAPS explosives probe to mitigate the effects of interferences from nonexplosives.

Technologies using the SCAPS for detecting toxic metals in the subsurface have also recently been transitioned from laboratory and limited field evaluations to the ESTCP for full demonstration and validation. A number of field demonstrations of the fiber-optic LIBS probe [NRaD], the downhole laser LIBS probe [WES], and the XRF probe [Naval Research Laboratory, WES] using side-by-side evaluations have been performed. Preliminary field evaluations have demonstrated that these technologies can detect low levels of metals in soils including Cr, Pb, Cu, and Fe. Under the ESTCP project, a direct comparison (performance and cost) among the three technologies will be performed, and the best technology will be transitioned to government and commercial SCAPS users.

7 CONCLUSIONS

The interfacing of chemical technologies with the cone penetrometer has made it possible to perform characterizations of many contaminated sites in a less intrusive, more cost-effective manner than performing the same investigation by the conventional method of drilling, sampling, and chemical analysis in the laboratory. The cone penetrometer is evolving from a device used only to gather geotechnical information about the subsurface to a tool that can also collect samples of groundwater, soil, and soil gas for chemical analysis and can provide in situ chemical detection. The most recent technological developments include the incorporation of on-line analytical and in situ chemical detection techniques into the cone penetrometer. It is apparent that a large number of probes have been invented that are capable of measuring inorganic and organic contamination in screening and quantitative modes over a wide range of concentrations; however, it is also apparent that many of these probes have not undergone the rigorous field demonstrations, validations, and implementation in site characterizations that will be necessary to obtain regulatory acceptance of the methodologies. To gain regulatory acceptance, data from the probes must be validated against data from verification samples that are collected and analyzed by accepted methods. The field validation should be performed at a variety of sites containing different soil and groundwater types to evaluate the effects of the sample matrix on the mechanical and chemical performances of the probe. Results from site characterizations performed by conventional methods of drilling, sampling, and laboratory analysis should then be compared at the same site with the results of characterizations performed with the cone penetrometer technologies to quantify improvements in the accuracy, speed, and cost of the site characterization.

ACKNOWLEDGMENTS

We thank our colleagues for providing valuable information on the cone penetrometer devices. The technical reviews by Dr Nancy A. Marley and Ms Candace M. Rose of Argonne National Laboratory and by Dr William M. Davis of the US Army Corps of Engineers Waterways Experiment Station are greatly appreciated. The assistance of Ms Eileen Brazelton of Argonne National Laboratory with editing is also greatly appreciated. The writing of this article was supported by the US Department of Energy under contract W-31-109-Eng-38 as part of the Characterization, Monitoring, and Sensor Technology Integrated Program of the Office of Technology Development, Assistant Secretary for Environmental Management (PVD), and by the Strategic Environmental Research and Development Program (SERDP), Washington, DC (ERC). The authors also wish to acknowledge SERDP, the Environmental Security and Technology Certification Program (ESTCP), the Army Environmental Center, and the Army’s Installation Restoration Research Program (IRRP) for funding the SCAPS sensor and sampler development and demonstration projects described in this article.

FIELD-PORTABLE INSTRUMENTATION

Electrochemical Sensors for Field Measurements of Gases and Vapors

James A. Cox and Scott D. Holmstrom
Miami University, Oxford, USA

1 Introduction

A challenge in designing chemical sensors that are suited to operate as stand-alone devices is that an attendant separation method is not convenient, so the detection system must be highly selective. An additional problem is that any chemical step that is associated with the measurement, such as conversion of the targeted substance (analyte) to a species amenable to producing a signal, must operate in a small, isolated environment without a reagent reservoir. In that the output of a sensor must be an electrical signal, electrochemical systems have less-complex designs than other sensors where the conversion of information from the chemical to the electrical domain requires two steps. Moreover, the attendant chemistry, if any, typically is simple. Yet, commercial electrochemical sensors are available for only a limited number of analytes, including H2S, O2, CO, SO2, NO, HCN, HCl, NO2, and Cl2, primarily because of the problem of attaining sufficient selectivity.

In this article, the scope of field applications of electrochemical sensors for gaseous chemical species is described. Field studies are broadly defined to include measurements both at remote sites and in environments where the stand-alone characteristic of these devices favors their use over conventional, bench-top instrumentation. An emphasis is placed on the direction of research in this field and on the analytical figures-of-merit that can be achieved.

Electrochemical sensors generally fall into one of three categories. Potentiometric devices have as their analytical signal the potential across a cell. Because the time required to develop an equilibrium potential is related to the resistance of the layer between the electrodes, the electrodes are separated by an ionic conductor, which can be a solid or a liquid. Amperometric sensors provide a

Sensors that utilize signals produced by redox of a targeted species (analyte) at an electrode under controlled potential, the conductance changes produced by contact of a chemical species with an electrolyte, or a change in the equilibrium potential of an electrode upon contact with an analyte are being employed in studies of gaseous samples of environmental, biomedical, and industrial interest. Changes in the work function of chemically modified field effect transistors (FET) also is a strategy related to both conductivity and potentiometry. Electrochemical sensors are fundamentally advantageous over other types in that they directly convert information from the chemical to the electrical domain, rather than requiring another transducer. Yet, few have found commercial application. The common types that are employed for field measurements of gaseous samples include devices to quantify oxygen, hydrogen sulfide, sulfur dioxide, oxides of nitrogen, hydrogen cyanide, hydrogen chloride, and chlorine. The limitation is not sensitivity; by this measure electrochemistry is among the best of the analytical measurement methods. Amperometric sensors accrue selectivity by control of the electrode potential along with control of the process by which the analyte partitions from the gas to the electrolyte. The latter is the primary means by which conductivity and potentiometry systems achieve sensitivity. These methods are not as selective as those in which a chemical reaction is incorporated in the sensor. The most selective electrochemical sensors employ an enzymatic reaction as part of signal production, but these are applicable to only a few analytes, such as alcohols, of importance in the gas phase.
signal from redox at the indicator electrode surface under controlled potential. In the third category, the signal is the conductivity of the electrolyte which changes in response to the analyte. Other types include galvanic cells and devices in which the signal is related to the work function of a coating, especially on a FET.

Electrochemical gas sensors often involve a two-step process, the partitioning of the analyte from the gas phase onto the electrolyte and the signal-generation step. The electrolyte can be a solid, a liquid, or a combination of the two. Its function is to provide an ionically conducting connection between the electrodes. With liquid-containing electrolytes, the partitioning is by dissolving the gas-phase analyte into the liquid. Most often, the signal generation of such sensors is by redox at an indicator (working) electrode. Unless the sensor design has a three-phase boundary among the gas, liquid, and electrode, the response time is slowed by mass transport of the liquid-phase analyte to the electrode. With solid electrolytes, a variety of signal-generation processes are employed. Here, partitioning is by adsorption. In cases such as the commercial SnO₂-based CO sensor, which operates at about 400 °C level and, hence, the threshold voltage of the device, a process that changes the resistance and/or material, a material, a process that changes the resistance and/or conductivity of the electrolyte which changes in response to the analyte. Other types include galvanic cells and devices in which the signal is related to the work function of a coating, especially on a FET.

Electrochemical gas sensors often involve a two-step process, the partitioning of the analyte from the gas phase onto the electrolyte and the signal-generation step. The electrolyte can be a solid, a liquid, or a combination of the two. Its function is to provide an ionically conducting connection between the electrodes. With liquid-containing electrolytes, the partitioning is by dissolving the gas-phase analyte into the liquid. Most often, the signal generation of such sensors is by redox at an indicator (working) electrode. Unless the sensor design has a three-phase boundary among the gas, liquid, and electrode, the response time is slowed by mass transport of the liquid-phase analyte to the electrode. With solid electrolytes, a variety of signal-generation processes are employed. Here, partitioning is by adsorption. In cases such as the commercial SnO₂-based CO sensor, which operates at about 400 °C level and, hence, the threshold voltage of the device. When redox is the signal-generation step, the response time and sensitivity is limited by mass transport in the solid, as detailed later. Solid-state systems often are based on a chemical reactions between the analyte and sensing material, a process that changes the resistance and/or work function of the device.

2 BACKGROUND

2.1 History

Electrochemical gas-phase sensors first became important with the development of the oxygen electrode. This sensor evolved from the simple measurement of dissolved oxygen by measurement of the current due to its reduction in a polarographic cell except that a platinum indicator electrode was used. To minimize interference from surface-active species in the sample, the Pt was coated with a membrane; however, Clark advanced the technology by isolating a film of supporting electrolyte from the sample with an oxygen-permeable membrane. As shown in Figure 1, this now-common design monitors analytes in either gas or liquid samples. The selectivity is accrued by the relative rates of diffusion of the analyte and the interferents through the choice of the membrane and the selection of the appropriate combination of the supporting electrolyte and applied potential. For example, by using a mixture of 0.1 M KCl and 0.01 M ZrOCl₂ as the supporting electrolyte, a mercury indicator electrode, an applied potential of −1.25 V vs Ag/AgCl, and an anion-exchange membrane as the barrier, the system serves as a sensor for NO₃⁻ and presumably for NO₂ in the gas phase.

A significant improvement in the general design in Figure 1 was the replacement of the film of liquid electrolyte with a solid polymer electrolyte (SPE). The use of SPEs originated in fuel cell and battery technology, but adaptation to sensors yielded robust systems with long-term stability if a reservoir is provided to keep the SPE wet. The SPEs are ion-exchange polymers such as Nafion, Tosflex, which are perfluorinated cation- and anion-exchange materials, respectively. Recent applications have employed porous electrode materials that were supported on the membrane, which exposes the electrode/SPE interface directly to the gaseous sample, thereby providing rapid response.

Solid-state gas sensors that are based on metal oxide electrolytes date to the early 1960s. An oxide such as ZrO₂ that is doped to provide mobile O²⁻ sites comprises a common form. One approach to measurement is to have the analyte perturb the O²⁻ population (e.g. chemisorption and decomposition of an alcohol yields H atoms that combine with O²⁻), thereby changing the conductivity. The electrolytes also can be configured to provide amperometric or potentiometric measurement. A major application of these sensors is the determination of oxygen, especially where operation at elevated temperature is required.

The process that generates the signal is the basis of the classification method in this chapter. With amperometric sensors, the signal is the current that is produced upon oxidation or reduction of the analyte at an electrode surface. In general, the current can be limited by the rate of the electron-transfer reaction or the rate of transport of the analyte to the electrode surface; however,
the former is not useful for analytical determinations. The rate of electron transfer is a function of applied potential. By applying a potential that is well-positive of the standard reduction potential, \( E^{0} \), the condition in which an oxidation is limited by mass transfer often can be achieved. For reduction to serve as the current-generating step, the applied potential is well-negative of \( E^{0} \). It should be noted that many electrochemical reactions that are predicted on the basis of \( E^{0} \) are too slow in the accessible potential range to provide a useful current. In this case, either a suitable electrocatalyst must be employed or some other means of sensing must be used.

Amperometric sensors operate under conditions in which the mode of mass transport to the electrode surface is diffusion. In this case the flux of the analyte, \( f \), is given by Equation (1):

\[
f = D \left( \frac{\partial C}{\partial x} \right)_{x=0} \tag{1}
\]

where \( D \) is the diffusion coefficient, \( C \) is the concentration of the analyte, and \( x \) is the distance from the electrode surface. For reliable measurements, the sensor must operate at steady-state. Because \( C \) is zero at \( x = 0 \) at the operating potential described above and the slope of the plot of \( C \) vs \( x \) near the electrode is nearly linear, the partial derivative in Equation (1) is proportional to the sample concentration. The analytical current, \( i \), is given by Equation (2):

\[
i = nFAd
\]

where \( n \) is the number of electrons transferred per mole; \( F \), the Faraday, and \( A \), the electrode area. So the concentration is related to current by Equation (3):

\[
i = \frac{nFADC}{\delta} \tag{3}
\]

where \( \delta \) is the boundary layer containing the gradient. This treatment is valid for a single phase, so in a gas sensor, where partitioning between phases can occur, it is necessary to assume that \( C \) in Equation (3) (i.e. the concentration in the electrolyte) is directly proportional to the concentration of the analyte in the gas phase in order to achieve linear calibration curves.

Potentiometric sensors are available in a wide variety of configurations, obviating a simple treatment of the signal-generating process. In the simplest case, the measured signal is the potential of an indicator electrode vs a reference electrode under equilibrium conditions, and the potential is related to concentration by the Nernst equation. For example, if \( \text{HCl}_{\text{gas}} \) is partitioned into an aqueous solution (receiver) contacted by a reference electrode and a Ag/AgCl electrode Equation (4),

\[
\text{Reference/receiver, AgCl/Ag} \tag{4}
\]

the \( \text{HCl}_{\text{gas}} \) is indirectly measured as the \( \text{Cl}^- \) produced. The system can operate as a concentration cell by selecting \( \text{Ag/AgCl} \) in contact with a standard concentration of \( \text{Cl}^- \) as the reference. The measured potential, \( E \), is given by Equation (5):

\[
E = \left( \frac{RT}{F} \right) \log \left( \frac{[\text{Cl}^-]_{\text{receiver}}}{[\text{Cl}^-]_{\text{standard}}} \right) \tag{5}
\]

A second simple system is configured as a \( pH \) electrode in contact with a thin film of solution; exposure to a gas with acid–base properties such as \( \text{CO}_2 \) changes the \( pH \) of the film. More complicated treatment is required when, for example, mixed potentials are developed, solid solution formation occurs, or the measured signal is the work function of a material. These will be treated in the description of applications in section 4. It should be noted that a common feature is that the measured signal is linear with respect to the logarithm of concentration, although over narrow ranges and at low concentrations the relationship approaches linearity without the logarithmic function.

Detection by conductivity is used in certain gas sensors that employ solid electrolytes. A report by Chakraborty et al.\(^9\) is illustrative of this class of sensor. A glass consisting of \( \text{Fe}_2\text{O}_3-\text{Sb–TeO}_2 \) showed semiconducting properties with charge-exchange occurring between mixed-valence iron sites. The d.c. conductivity in the temperature range 463–598 K was investigated in atmospheres containing various amounts of \( \text{O}_2 \). A decrease in conductivity upon exposure to \( \text{O}_2 \) was attributed to a decrease in \( \text{Fe}^{2+} \) from Equation (6):

\[
\text{O}_2(\text{adsorbed}) + \text{Fe}^{2+} \longrightarrow \text{O}_2^- + \text{Fe}^{3+} \tag{6}
\]

which attenuated charge-exchange. Not considered was an ionic conductivity mechanism with \( \text{O}_2^- \) as the charge carrier. As noted above, \( \text{O}_2^- \) often is considered the charge carrier in metal oxide systems such as \( \text{SnO}_2 \) and \( \text{ZrO}_2 \). In this regard, sensing of fuel gases with such devices has been attributed to consumption of \( \text{O}_2^- \) by the analyte.

### 2.3 Analytical Performance

Important factors in evaluating gas sensors include the detection limit (DL), sensitivity, linear dynamic range (LDR), response and recovery times, selectivity, short-term stability (repeatability), and long-term stability. The DL is the minimum concentration of the analyte that can be observed with a stated degree of certainty. Operationally, it is the concentration that yields a blank-corrected signal that is a factor, \( k \) times the standard deviation (SD) of the blank; generally, \( k = 3 \). Assuming that the blank uncertainty is random, that the measured
SD is representative of the population distribution, and that two measurements are required (namely, the blank and the sample) which is typically used, \( k = 3 \), provides detection at the 98.3% confidence level.\(^{10}\) Published values of DL are useful as guides to the range over which a sensor may be used, but practical measurements at the DL generally are not possible. The DL is not a significant factor for sensors that monitor major components, but it is crucial for monitoring toxic materials.

The response time is generally reported as \( T_{90} \) or \( T_{50} \), which are the times to reach 90% and 50% of the steady-state signal, respectively.\(^{11}\) The limiting factor can be the sampling step or the measuring step. The former occurs with a barrier between the sample and the indicator electrode. For example, in many designs, the analyte must diffuse through a membrane and/or through a layer of electrolyte prior to reaching the indicator electrode. The time constant in this case is related to \((\Delta x)^2 / D\) where \( \Delta x \) is the thickness of the barrier. Typical \( D \)-values are in the ranges ca. \( 10^{-1} \text{cm}^2\text{s}^{-1} \) in the gas phase, \( 10^{-3} \text{cm}^2\text{s}^{-1} \) for an aqueous system, and \( 10^{-5} \text{cm}^2\text{s}^{-1} \) or smaller in a solid. Values between liquid and solids are observed in SPEs such as Nafion\(^{8}\). The most rapid responses are observed with porous barriers where the pores are air-filled. Here, a gas/electrolyte/electrode three-phase boundary exists, and the response time becomes limited by the electrode response. A detailed analysis of a commercial CO detector was performed.\(^{11}\) The diffusion path consisted of 0.2 cm through a sintered disk, 0.4 cm through air, 0.03 cm through a backing membrane, and 0.01 cm through an electrode membrane; the respective \( D \)-values in these media were 0.15, 0.21, 7 \( \times \) \( 10^{-3} \), and \( 2 \times 10^{-3} \text{cm}^2\text{s}^{-1} \), respectively. The \( T_{90} \)-value under these conditions was limited primarily by the electrode response with some evidence of a contribution from diffusion. This result suggests that in any system with a direct air-path to the electrode, \( T_{90} \) will be related to the electrode response, whereas in a system that involves mass transport of the analyte through an SPE with liquid-filled pores or through a solid, diffusion will be the factor that limits response time.

With an amperometric sensor, \( D \) also influences the sensitivity, which is the slope \((m)\) of a linear calibration curve (see Equation 3). Because the units of a calibration curve are variable, the value of \( m \) does not have much value in terms of comparing various sensors for a given analyte. For such comparisons, a preferable parameter is the analytical sensitivity, which is \( m/SD \) (where \( SD \) is the standard deviation). LDRs also must be compared with caution in that a consensus definition is not available. Often the LDR is taken as the region of the calibration curve where the departure from linearity is less than 5%. Reports of selectivities and lifetimes also are not subject to defined standards.

### 2.4 Contributions of Materials Science to Sensor Development

Recent advances in electrochemical sensor technology have resulted primarily from new materials. An early improvement was the substitution of an SPE for an aqueous solution in the general design of an amperometric sensor (Figure 1). Nafion\(^{8}\) is the most widely used SPE. The backbone is tetrafluoroethylene, and the structure contains side-chains of perfluorinated vinyl ethers with terminal sulfonic acid functionalities that provide strongly acidic cation-exchange sites. It is highly ordered and stable in aqueous solution under a wide range of acid–base and redox environments. The sulfonic acid sites generally are considered to exist in inverse micelles that are connected by neutral channels, but some studies have considered the ionic sites to be distributed along continuous channels.\(^{12}\) Ionic conductance under dialysis conditions occurs with an activation energy of about 25 kJ mol\(^{-1}\), which is evidence for the inverse micelle structure in Nafion\(^{8}\) wetted with aqueous solution.\(^{13}\)

A limitation on the use of Nafion\(^{8}\) as the electrolyte is the influence of humidity on the response. Lee et al.\(^{14}\) addressed this problem systematically. A sensor for CO was used where the current due to its oxidation at a Pt electrode provided the signal; a Nafion\(^{8}\) SPE provided the current path across the cell. The sensitivity and the background current were functions of the humidity of the sample, in part because swelling as the humidity increases causes an increase in the conductivity of the SPE. Moreover, because the oxidation of CO is dependent upon water (Equation 7),

\[
\text{CO} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \quad (7)
\]

they surmised that the rate of oxidation of CO increases with water content. However, other factors such as the rate of diffusion of H\(^+\) away from the indicator electrode and the diffusion of CO within the Nafion\(^{8}\) can be important.

Solids prepared by sol–gel chemistry are alternatives to Nafion\(^{8}\) as electrolytes for gas sensors. One attractive feature is that they are suited as hosts for a variety of chemical species such as enzymes and complexing agents, whereas Nafion\(^{8}\) and other SPEs host materials primarily by ion-exchange reactions. The products of sol–gel processes are polymers with repeating oxygen-bridged metal systems such as silica, vanadia, alumina, and titania. A typical process is the hydrolysis of tetraethyl orthosilicate (TEOS) to a colloidal sol followed by condensation into a loosely crosslinked gel. With aging, during which water and ethanol are expelled, a glass-like solid termed a xerogel is formed. Unless the material is fused, the xerogel is porous and contains residual water both in the pores and...
bound to the backbone. An important characteristic is that during the gelation and drying steps, species larger than the pore diameters, which range from a few Angstroms (1 Å = 0.1 nm) to the nanometer scale (depending on the preparation procedure), are encapsulated by a self-templated mechanism; hence, the activities of substances such as enzymes are the same in xerogels as in homogeneous aqueous solutions.\(^{(15)}\) Detailed descriptions of sol–gel processes are widely available.\(^{(15–17)}\)

With CO as the analyte, an amperometric sensor with a silica xerogel as the electrolyte provided a sensitivity that was independent of humidity over the range 9–76%,\(^{(18)}\) which is in marked contrast to the above-described system with Nafion\(^{\circledR}\) as the SPE. The sensitivity was unchanged even though the water content of the xerogel ranged from 20 to 50%. Apparently, the water content was sufficiently high to yield a pseudo-first-order rate of oxidation. It is interesting that the diffusion of CO through the xerogel was also constant over this range. In this regard, a three-phase boundary was not present, so the CO diffused through a 5-µm layer of the xerogel to reach the indicator electrode. A similar result was observed with a silica-based amperometric sensor for gaseous hydrogen peroxide.\(^{(19)}\)

Materials science also influences the design of electrocatalytic systems. Conducting composites that are doped with catalysts are emerging as important electrode materials. Sampath and Lev\(^{(20)}\) described a composite electrode made from a combination of carbon powder, Pd, and an organically modified silicate. The latter was a product of sol–gel chemistry, but with methyltrimethoxysilane as the precursor. Various enzymes such as glucose oxidase and lactate oxidase were encapsulated in the composite. In contact with liquid samples, \(T_0\)-values of 15 s were obtained, and stable responses for up to 120 days were observed. Although not used for gas sensing, extension to samples such as alcohols (using an appropriate enzyme and SPE) can be envisioned. Other new materials as electrocatalytic indicator electrodes include metal-doped glassy carbon; conducting composites containing platinum group metal oxides, metal phthalocyanines, or porphyrins; and xerogels or conducting organic polymers with dispersed platinum group metal centers. Such electrodes are described in a review.\(^{(21)}\)

3 SCOPE

In this section, the areas of application of electrochemical gas sensors are described. Emphasis is placed on describing the most important analytical performance characteristics for each of the sample types.

3.1 Environmental Monitoring

Perhaps the most challenging area of field applications of electrochemical gas sensors is environmental monitoring. Here, trace level determination is the dominant theme.

in that the analytes that are monitored typically are hazardous. Exacerbating the challenge of environmental analysis is the restriction on the type of methodology that can be employed. While mobile laboratories and grab sampling of stable species allow the use of sophisticated measurement technology, there is a need for the further development of remote sensors. For example, long-path infrared spectroscopy has been used for on-site measurement of the ratio of CO to CO$_2$ emission from vehicles on roadways,$^{22,23}$ but using this technology to continuously monitor air quality at multiple sites has prohibitive costs. Electrochemical sensing is relatively inexpensive, particularly if coupled with micromachining technology by which lithography can be used for large-scale production of platforms that contain the instrumentation and data transmission electronics.$^{24}$

DL and long-term stability are the most important of the analytical performance criteria for remote application of environmental sensors. The former needs to be related to values such as the Occupational Health and Safety Standards. Table 1 is a summary of reported DLs and interferents for selected electrochemical gas sensors that are under development, along with values for permissible exposure limits.

The need for remote sensing of environmental samples is most compelling for analytes that lack the stability for grab sampling with subsequent transport to an analytical laboratory. Ozone, which is among the strongest oxidizing agents, provides an example. Ozone is of environmental significance in part because it causes plant damage as well as degradation of plastics and rubbers. Moreover, it is considered a cause of respiratory disorders.$^{36}$

Electrochemical determinations of ozone typically are based on its reduction at a gold electrode (Equation 8).

$$\text{O}_3 + 2e^- + 2\text{H}^+ \rightarrow \text{O}_2 + \text{H}_2\text{O} \quad (8)$$

At a pH less than one, the onset of reduction occurs at approximately 1.0 V vs saturated calomel electrode (SCE). A direct adaptation of this reaction to amperometric sensing was reported by Schiavon et al.$^{30}$ Here, the interface between the indicator electrode and the gas sample was a Nafion$^\text{®}$ ion-exchange membrane that was wetted by contact to a 0.1 M HClO$_4$ reservoir (Figure 2). The sensor was operated at 0.5 V vs SCE. Chlorine and oxides of nitrogen interfere in that they are reduced at this potential. The system provided a LDR of four orders-of-magnitude, a DL of 224 ppbv, and a stability of 2 months.

The DL of the above sensor is above the ceiling level of 0.1 ppmv for O$_3$, but for many applications detection at the threshold level is required. One route to improving the DL, albeit at the expense of simplicity of instrumentation, without changing the signal-generating chemistry was to employ pulse voltammetry at a gold electrode.$^{29}$ Here, the sensor design was similar to that in Figure 1; a gas permeable membrane was placed over a lens paper that was used to immobilize an electrolyte film to which the electrodes were contacted. The ozone was sampled from the air into a solution that contacted the sensor via a frit, so a reservoir to keep the lens paper wetted was not necessary. Rather than apply the reduction potential continuously, a value where no reaction occurs was applied to allow O$_3$ to accumulate for 5 s. Next, the electrolysis potential was applied, and the current was measured after 100 ms. After several cycles, a steady-state current was obtained. The $T_{90}$ value was 7 s with a 1-mil dimethylsilicone gas permeable membrane. This mode resulted in a 50-fold improvement in the DL relative to constant potential application. The strategy of employing a preconcentration step does not address the problem of selectivity. Any component of the sample that is electroactive at the measurement potential (in the range 0.5 to 0.7 V vs SCE in these studies) will interfere.

The above reports illustrate the challenges presented by field studies of environmental samples. Section 4 includes descriptions of other studies aimed at development of ozone sensors and of sensors for other analytes of interest in environmental science.

3.2 Biomedical Applications

Most biomedical analysis is performed in a dedicated laboratory; an important exception is monitoring of glucose in blood. Moreover, analysis of gaseous samples is less common than studies on liquid samples. Field determinations of gaseous biomedical samples primarily involve emergency or law enforcement measurements of analytes related to respiration, including the indirect determination of ethanol in blood. In contrast to environmental monitoring, trace analysis and unattended measurements by remote sensors are not very important; instead, linear response, reproducibility, response and
recovery times, and freedom from interference are high priorities in terms of analytical performance criteria.

A representative example of a sensor applicable to respiration studies is the report by Tierney and Kim of amperometric sensors for the determinations of NO and O2 and a potentiometric sensor for the determination of CO2. Of importance in this study is the employment of micromachining technology in devising sensors with fast response times. Specifically, porous platforms are used in conjunction with porous electrodes to enhance the formation of a three-phase boundary, which allows mass transport to occur in air rather than water. A deleterious effect of this facile mass transport is that the electrode reaction rather than mass transport is current-limiting, so the calibration curve is not linear. Also, the redox of some analytes yields products that poison the electrode surface and/or the SPE; in these cases, diffusional barriers sometimes are employed to lower the rate of electrolysis, which, in turn, increases the long-term stability. With O2 as the analyte, the T90 is 300 ms and a calibration curve, albeit nonlinear, is obtained over the range 10–100% O2. Interference of such species as N2O and halothane, which are the two anesthetics that have known electrochemical activity, is not observed at the operating potential, −0.55 V vs Ag/AgO. Nitric oxide was determined in an analogous manner except that the sensing reaction was given by Equation (9):

\[
\text{NO} + 2\text{H}_2\text{O} \rightarrow \text{NO}_3^- + 4\text{H}^+ + 3e^- \quad (9)
\]

A calibration curve was obtained over the range 20–100 ppmv, and the DL, which was calculated on the basis of \( k = 2 \), was 5 ppmv. The T90 was 330 ms, and the time to return to the baseline upon flushing was 550 ms.

For the potentiometric measurement of CO2, Tierney and Kim modified the Severinghaus-type sensor, which utilizes pH measurement in an electrolyte film separated by an air-gap from the sample. Iridium oxide was used for the pH measurement, and the micromachined porous system was used to enhance mass transport. Moreover, carbonic anhydrase enzyme was included in a commercially available hydrogel to reduce response times for the potentiometric sensor; in this regard, the use of the enzyme circumvents the slow hydrolysis of CO2 that otherwise limits the response time. A calibration curve yielded a linear correlation between potential and \( \log(\%\text{CO}_2) \) over the range 1–10% CO2. The T90 was 1690 ms, and the system was stable for up to 8 h.

An amperometric sensor for ethanol in breath was developed on the basis of amperometry in a cell with a SPE. The indicator electrode was porous gold that was supported on Nafion®. The gold was exposed directly to the gas sample. A solution of 1 M NaOH was in contact with the backside of the Nafion®. This allowed pre-oxidation of gold to a catalytically active oxide at potentials below that required for the production of the analytical signal. The oxidation of ethanol yielded a product that fouls the electrode surface. Hence, pulsed electrochemical detection (PED) was used to obtain the optimum performance. In PED, the electrode potential was pulsed in a sequence that provided for the following:

1. stripping the gold oxide and accumulated products by reduction;
2. forming the catalytic gold oxide; and
3. causing the oxidation of ethanol.

The 95% response time was estimated as 1 s, and the signal returned to the baseline in 20 s when the system was flushed with nitrogen. The DL of the sensor, 1 ppmv, is sufficient for the biomedical or the forensic determination of ethanol in breath. As described, the apparatus is not amenable to field measurements, but if combined with a micromachined platform and the use of microelectronics to apply, measure, and transmit electrical signals, a portable, low-cost system can be projected.

A summary that delineates the scope of electrochemical sensors for gaseous samples of interest in biomedical

3.3 Sensors in Process Monitoring and the Work Place

Owing to the enormous number of industrial settings and potential analytes in the workplace, a simple set of desired characteristics for these sensors cannot be defined. Applications range from monitoring a reactant or product on the order of percent composition to the determination of a toxic by-product on the order of ppb. Also, the operating conditions such as temperature, relative humidity, and pH vary greatly. The scope of applications and approaches being used for development of sensors for such uses is illustrated below and in Table 3.

Sulfur-containing compounds, a class that includes some of the most toxic compounds known, are common by-products of industrial processes. For example, hydrogen sulfide gas has a ceiling limit of 15 ppmv (American Conference of Governmental Industrial Hygienists, 1996); the required DL for H₂S is well below this value. An amperometric sensor for H₂S was developed using a carbon indicator electrode that was doped with the electro-oxidation catalyst, cobalt phthalocyanine and using a sodium phosphate–agarose hydrogel as the electrolyte. With the indicator electrode at 0.4 V vs Ag/AgCl, a linear amperometric response to H₂S over the range 2–18 ppmv was obtained. Extension to other sulfur compounds and the details of the mechanism are in section 4.1.

Hydrogen peroxide has a TLV of 1 ppmv. A variety of electrochemical sensors have been developed for the detection of trace levels of gaseous hydrogen peroxide. One example is shown in Figure 3. A diffusion scrubber is employed to introduce the hydrogen peroxide into a bulk electrolyte solution. In this design, the analytic gas and the recipient buffer are flowing in a countercurrent fashion. The DLs obtained with this sampler depend on solution volume, flow rate, and preconcentration time. With a 9-min enrichment, the DL was below 1 ppbv.

A more compact design of an amperometric sensor for H₂O₂ is based on the diffusion of hydrogen peroxide gas into a silica solid electrolyte made by base-catalyzed sol–gel chemistry. A 10-µm film of silica coated coplanar disks of Pt, which served as the indicator and auxiliary electrodes, and Ag/AgCl, which was the reference electrode. The wires were sealed by epoxy in a 3.5-mm housing. The silica contained MgCl₂, which acted as an internal humidistat and provided ionic conductivity. The samples were the gas phase above solutions of various concentrations of H₂O₂ in water. The concentrations were calculated from thermodynamic data. The signal was obtained by applying a potential pulse after a prescribed analysis in the field is in Table 2. Detailed descriptions of selected systems are in section 4.
ELECTROCHEMICAL SENSORS FOR FIELD MEASUREMENTS OF GASES AND VAPORS

preconcentration time. The DL was 10 ppbv, and the LDR was 96–5400 ppbv.

Species such as H⁺, O₂, and H₂ that influence the rate of corrosion or are concerns regarding the potential for explosions are important in certain industries. Monitoring is complicated if it must be performed at high temperature. A high-temperature potentiometric sensor for H₂ was developed that employed a solid electrolyte of 9% Y₂O₃ in zirconia and a fluorocarbon-coated Pt or Pd indicator electrode. A linear correlation between potential and log(%)H₂ was shown from 0.001 to 100% H₂ at 300 °C. In the presence of O₂ above 0.002%, the potential of the sensor response increased linearly with log(%)O₂. When ion-beam sputtered electrodes were employed with a thickness of 150 nm, a response time on the order of 200 s was reported.

Sensing O₂ at high temperature also is of concern in monitoring combustion. An O₂ sensor based on conductivity changes in SrTiO₃ at 1000 °C was developed to monitor the exhaust of internal combustion engines. The response time was 5 ms whereas with common ZrO₂-based systems it is 100 ms.

A potentiometric sensor capable of monitoring CO₂ at high temperatures was based on a solid electrolyte of Li₂CO₃—Li₂PO₄—LiAlO₂ with LiCoO₂—Co₃O₄ serving as a reference electrode. Various CO₂ concentrations were introduced at a rate of 100 cm³ min⁻¹. A steady-state response in one minute was reported at 400 °C. Although the DL was not reported, a linear response with respect to the logarithm of CO₂ concentration was shown for 10⁻²–10⁴ ppmv. The sensor was stable for one month. Oxygen was a significant interferent; a linear dependence of potential on the logarithm of the O₂ level was demonstrated.

Monitoring ethylene is important in several industries, including agriculture where it is important in ripening of produce. An amperometric sensor for ethylene was developed through the chemical deposition of gold onto a Nafion® SPE. The gold electrode faced the sample gas; a solution of 0.5 M H₂SO₄ was an internal electrolyte in contact with the opposite side of the Nafion® membrane. Relative responses reported for acetylene, NO, NO₂, and SO₂ were 7.4, 1.8, 0.3, and 2.5, respectively, but these species are not expected to be present at significant concentrations in agricultural facilities. No responses were reported for ethanol, acetaldehyde, and carbon monoxide. A similar sensor was developed for the detection of acetylene in industrial settings. Rather than using a constant potential detection as was done for ethylene, PED was performed to minimize the poisoning of the electrode surface by the oxidation products. No significant interferents were reported using PED for NO, NO₂, SO₂, and ethylene.

The above citations suggest that for measurements at room temperature the common strategy is to employ amperometric sensors with a SPE, which often is employed in conjunction with a porous electrode to develop a three-phase boundary. At elevated temperature, potentiometry and conductivity associated with inorganic electrolytes such as metal oxides are the typical bases of sensing.

3.4 Other Applications

The detection of analytes for purposes other than those previously categorized includes forensics. One of the largest applications for gas-phase sensors in forensics is for the determination of alcohol in breath. Electrochemical sensors for ethanol often employ enzymes as catalysts. An example of such a sensor is one developed for the determination of primary alcohols consisting of carbon chain lengths from two to six. In this case, alcohol dehydrogenase (ADH) that is immobilized on an acetylcellulose membrane is the catalyst. The catalyst is separated from the sample solution by a gas-permeable membrane (Figure 4). This membrane serves both to prevent the enzyme from leaching into the sample solution and to provide an air-gap between the sample and electrode. The latter improves the selectivity because only volatile substances reach the electrode surface. The liquid layer between the membrane and the electrodes contains an electron-mediator. The mechanism for the generation of the analytical signal is given by Equation (10), which is enzyme-catalyzed and Equation (11), which occurs at the indicator electrode.

\[
\text{C}_2\text{H}_5\text{OH} + 2\text{Fe(III)} \rightarrow \text{CH}_3\text{CHO} + 2\text{Fe(II)} + \text{H}_2 \quad (10)
\]

\[
\text{Fe(II)} \rightarrow \text{Fe(III)} + e^- \quad (11)
\]

The current produced by Equation (11) was directly proportional to the concentration of C₂H₅OH over a wide range of conditions. Among the factors in obtaining
a wide LDR and low DL was the choice of the gas-permeable membrane. A comparison was made between polytetrafluoroethylene (PTFE) and a silicone rubber membrane. With the PTFE membrane, the upper limit of the linear range was 0.08 mM, whereas with the silicone rubber membrane, a linear range up to 1.8 mM was reported. The selectivity of this sensor was good. No response to 0.1 mM solutions of methanol, acetic acid, ascorbic acid, and glucose was observed, but a 0.1 mM acetaldehyde solution gave a 2% response relative to ethanol. It was demonstrated that the sensor functioned continuously for more than two weeks; however, after nine days, the sensitivity dropped to 85% of its original response. Although the data were reported for the determination of ethanol vapors above a solution, extension to its measurement in breath is straightforward.

An electrochemical sensor that was applied to the measurement of ethanol in breath has been reported. This amperometric system utilized a SPE-supported porous gold indicator electrode, which faced the sample. The measurement was by PED. The response (95% of steady-state) and recovery times were 1 and 20 s, respectively. The DL, 1 ppmv, is more than a factor of a hundred lower than the level needed to measure ethanol in breath.

Electrochemical sensors for gases and vapors in forensic science for analytes other than ethanol are not common at present. Yet, numerous other applications can be envisaged. The measurement of any analyte that can be converted to an electroactive compound with a high vapor pressure can be accomplished. For example, many enzymatic reactions yield carbon dioxide or ammonia which subsequently can be determined by electrochemical sensors.

### 4 SELECTED APPLICATIONS OF ELECTROCHEMICAL GAS SENSORS

In the previous section, reports that illustrated the type of field applications where electrochemical gas sensors are employed were emphasized. Here, examples of more fundamental studies that can be applied directly to monitoring in the field are provided. Consistent with this objective, the present section is organized according to the chemistry of the process that provides the signal.

#### 4.1 Amperometric Sensors

Measuring the current at constant potential as a function of concentration is the dominant strategy for electrochemical sensing at other than elevated temperature. This approach benefits from the high signal-to-background ratio that is developed because the background generally is very low. The basic sensor design is very simple (see Figures 1 and 2). The electrolyte that bridges the three electrodes is usually a solid such as an ion-exchange polymer or a material prepared by sol–gel chemistry. A limitation of amperometric sensors is that the vast majority of chemical species that are thermodynamically predicted to undergo redox at an electrode in an accessible potential range are electrochemically silent because of unfavorable electron-transfer kinetics. Hence, investigations on electrocatalysis often are required prior to the development of an amperometric sensor for a given analyte. A related approach is to use enzymatic reactions to convert the analyte to a substance that is electrochemically active, a strategy that also provides a degree of selectivity to the resulting sensor.

Enzymatic reactions prior to amperometric detection have been reported for a variety of compounds. An important example is an amperometric sensor for phenol vapors. In one design, the diffusion of molecular oxygen as well as phenol vapors across a membrane separating the sample gas from the electrode system was used. The biosensor consisted of two layers: the barrier membrane composed of a carbon material modified with PTFE and a Nafion membrane that contained the enzyme, tyrosinase. The design allowed the enzyme layer to contact an electrolyte solution. The enzymatic reaction is shown in Equations (12–14):

\[
\text{O} + \text{O}_2 \rightarrow \text{HO}_2 (12)
\]

\[
\text{OH} + \text{O}_2 \rightarrow \text{OOH} (13)
\]

\[
\text{O} + 2\text{e}^- + 2\text{H}^+ \rightarrow \text{HO}_2 (14)
\]

The analytical signal for the sensor is produced from the electrochemical reduction of the $\text{o}$-quinone. The activity was retained for more than 20 days. The standards were prepared by headspace methods. That is, solutions of known concentration of phenol were prepared and sealed. After equilibration between the liquid and gas phases in the vials, the vapor was sampled by puncturing septa with a syringe. A DL of approximately 1 ppmv was estimated from the calibration curve. The sensor suffered from a response time on the order of several minutes.

A more general approach to electrocatalysis in amperometric sensing is to use electron-transfer mediation. Here, a redox couple that undergoes facile electron-transfer at
ELECTROCHEMICAL SENSORS FOR FIELD MEASUREMENTS OF GASES AND VAPORS

an electrode is selected as a catalyst Equations (15) and (16). Generally, it is immobilized on the electrode surface, but it also can be immobilized in the SPE in contact with the indicator electrode. Assume the mediator couple is

\[ M + e^- \rightleftharpoons N \]  
(15)

and that the analyte, A, is not electroactive even though thermodynamically

\[ B + e^- \rightleftharpoons A \]  
(16)

If the \( E^0 \) values for Equations (15) and (16) predict that

\[ M + A \rightleftharpoons N + B \]  
(17)

the electrochemical oxidation of A can be achieved by immobilizing the mediator couple (M, N) at the electrode surface and controlling the electrode potential so that M is the primary species. Now, introducing A to the sensor causes the momentary conversion of some of the M to N. At that electrode potential N is immediately re-oxidized to M, yielding a current. Clearly, the oxidation current is related to the concentration of A. This indirect oxidation of A follows the same quantitative relationship of current to concentration as the direct electrolysis.

An example of a mediated oxidation is the use of cobalt phthalocyanine as the mediator in a sensor for the determination of sulfur-containing compounds as described in section 3.3.(43) The proposed reaction when \( \text{H}_2\text{S} \) is partitioned from a gaseous sample into a basic electrolyte is shown in Equations (18) and (19):

\[ 2\text{HS}^- + 2\text{Co}^{2+} \rightleftharpoons 2\text{Co}^+ + \text{H}_2\text{S}_2 \]  
(18)

\[ \text{Co}^+ \rightleftharpoons \text{Co}^{2+} + e^- \]  
(19)

The mechanism of methanethiol detection was the same with the exception that it was obtained at a higher pH. The general mechanism of mediation was explained for the oxidation of an analyte; however, the analogous reactions serve to promote reduction. For example, the detection of dimethylsulfide was based on Equations (20) and (21):

\[ 2\text{H}^+ + \text{CH}_3\text{SSCH}_3 + 2\text{Co}^+ \rightleftharpoons 2\text{Co}^{2+} + 2\text{CH}_3\text{SH} \]  
(20)

\[ \text{Co}^{2+} + e^- \rightleftharpoons \text{Co}^+ \]  
(21)

where the reduction of \( \text{Co}^{2+} \) established the surrogate current for the reduction of \( \text{CH}_3\text{SSCH}_3 \).

Immobilized Fe(III,II) centers, which were in the form of phenanthrolinium complexes served as electron mediators for the oxidation of \( \text{NO}_2 \).(31) The interesting aspect of the sensor design involved immobilizing the centers by electropolymerization of a film of the mediator.

The reaction primarily responsible for the current is probably given by Equation (22):

\[ \text{Fe(III)} + \text{N(IV)} \rightleftharpoons \text{Fe(II)} + \text{N(V)} \]  
(22)

although the authors did not list this as the operative mechanism. Detection of \( \text{NO}_2 \) down to 2 ppbv was reported and the calibration curve was linear up to 25 ppbv. Provided that the electrode was kept in contact with the electrolyte, the performance was constant for one month. Interferents listed were \( \text{Cl}_2 \) and \( \text{SO}_2 \). Of importance is that \( \text{N}_2\text{O} \) did not provide a signal at the operating potential, and \( \text{NO} \) only gave a signal when it constituted nearly 100% of the sample gas.

The simultaneous determination of \( \text{NO} \) and \( \text{NO}_2 \) was achieved with a commercial design (Back Cell®) in which gold deposited on porous alumina comprised the indicator and auxiliary electrodes.(35) The direct oxidation of these species generated the current. At 0.3 V vs a Pt quasi-reference electrode, the sum of these two species was determined. At −0.3 V, \( \text{NO}_2 \) alone was measured. By subtraction, concentrations of \( \text{NO} \) and \( \text{NO}_2 \) up to 7000 ppmv and 9000 ppmv, respectively, were determined, but DLs were not reported. The \( T_{90} \) was 1.51 s, and the baseline recovery time (to 90% of the original value) was 1.27 s.

An amperometric sensor for simultaneous measurement of \( \text{NO} \) and \( \text{NO}_2 \) that did not rely on subtraction was one based on protonic conduction through \( \alpha \)-zirconium acid phosphate.(34) The pellicular zirconium phosphate served as a solid-state proton conductor. Gold or graphite was the indicator electrode. Current–potential curves indicated that the reduction of \( \text{NO}_2 \) and oxidation of \( \text{NO} \) Equations (23) and (24) occurred at different potentials.

\[ \text{NO}_2 + \text{H}^+ + e^- \rightleftharpoons \text{HNO}_2 \]  
(23)

\[ \text{NO} + \text{H}_2\text{O} \rightleftharpoons \text{HNO}_2 + \text{H}^+ + e^- \]  
(24)

Graphite provided the superior sensitivity with \( \text{NO}_2 \) as the analyte. A DL of 0.01 ppmv and a linear range up to 15 ppmv were reported for measurements performed at constant potential. A DL of 0.2 ppmv and an upper linear range of 15 ppmv were reported for the determination of \( \text{NO} \) at a gold electrode, but in this case, a pulsed potential was employed to help discriminate the \( \text{NO} \) signal from that produced by \( \text{NO}_2 \).

For biomedical applications, a more rapid response to \( \text{NO} \) is important in that it has a half-life in the presence of \( \text{O}_2 \) of 5–6 s. The same reactivity, when coupled with the envisaged future need for field measurements of \( \text{NO} \), presents a compelling case for further improvement of sensors for this gas. A promising approach is the use of a bilayer of Nafion® and cellulose acetate as a barrier between the sample and the electrode surface.(39)
The hydrolyzed cellulose acetate layer, which is in direct contact with the sample, serves as a size-selective barrier, whereas Nafion®, which is an anionic polymer, acts as an anion exclusion membrane. A steady-state response to NO was achieved in 20 s. Perhaps the substitution of Nafion® with a porous membrane will improve the response time to a practical value for determinations of NO in biomedical samples.

Phosphine (PH₃) and arsine (AsH₃) are extremely toxic gases produced by several industrial processes. An amperometric sensor for these species was developed using gold that was plated onto a PTFE membrane as the indicator electrode. An inner solution of sulfonic acid was the electrolyte; it contained the reference and auxiliary electrodes. The sensor was selective over ethanol, methanol, isopropyl alcohol, acetone, and toluene. The gas phase directly contacted the gold electrode. The DLs were 0.01 ppmv, and the LDRs extended to 1.1 ppmv for arsine and phosphine. The sensor also had a long lifetime; after 6 months of continuously monitoring air, the sensor still maintained more than 80% of its original response.

Electrochemical sensing of hydrogen peroxide can be based on either its reduction or its oxidation. For studies of gases, the oxidative approach is preferred because O₂ reduction generally overlaps that of hydrogen peroxide. An amperometric sensor was developed that employed a silica xerogel prepared by base-catalyzed sol–gel chemistry, which ensured that the pH of the pore liquid in the gel promoted formation of HO₂⁻, which is the electroactive species. A thin film of silica was cast on a three-electrode system in which platinum served as the indicator and auxiliary electrodes and silver served as the reference electrode. A LDR spanning three orders of magnitude and a DL of 10.2 ppbv were reported. The hydrogen peroxide vapors were introduced to the sensor via the headspace method (described above). The sensor also was applied as a gas-phase monitor of H₂O₂ released from the reaction of glucose and glucose oxidase enzyme (GOx) in O₂-saturated solution.

Amperometric sensing of ozone is related to that of hydrogen peroxide. As discussed in section 3.1, electrochemical O₃ sensors typically employ oxidation at a gold electrode to produce the signal. An alternative design employed a silver iodide disk as a solid electrolyte pressed between platinum gauze and silver electrodes. In this case, the response is from a galvanic reaction, not electrolysis at an applied potential. The sensor design is shown in Figure 5. The suggested mechanism for the response is shown in Equations (25–27):

\[
2\text{AgI} + \text{O}_3 \rightarrow \text{Ag}_2\text{O} + \text{I}_2 + \text{O}_2 \quad (25)
\]
\[
\text{I}_2 + 2e^- \rightarrow 2\text{I}^- \quad (26)
\]
\[
\text{Ag} \rightarrow \text{Ag}^+ + e^- \quad (27)
\]

A DL of 1 ppbv was reported, and a linear response was obtained for ozone levels up to 0.5 ppmv. The sensor responds to NO₂ as well as O₃, so they are mutual interferents.

A galvanic cell for the determination of NO₂ was reported using a nitrite sodalite electrolyte sandwiched between silver and gold electrodes. The sensor had a linear range of 3.03 × 10⁻⁴ to 6.39 × 10⁻² atm; the DL was not reported. An important feature of the sensor was that the response was independent of the oxygen content of the sample gas.

Galvanic sensors have limited appeal relative to amperometric systems based on a constant applied potential. As in any battery that is producing current, reagents at both electrodes must be replenished. But perhaps a greater problem is the DL. The anodic and cathodic currents must be the same, so the potential will vary to values that provide a reactive species. At low concentrations of the analyte, the reactive species will be an interferent.

4.2 Potentiometric Sensors

Potentiometry is an equilibrium method; no current passes through the cell during the measurement. The
potential difference between two electrodes constitutes the measured signal. To relate this signal to the concentration of an analyte, one of the half-cells is of a composition that provides an invariant potential (i.e. it is a reference electrode). In one measurement scheme, the other half-cell includes a redox electrode. For equilibrium to be reached, both the oxidized and the reduced form of the half-cell species need to be present. Moreover, for meaningful analytical data to be obtained, the concentrations in both oxidation states must be high enough to avoid a mixed-potential, which is a situation where more than one redox couple contributes to the potential.

Mixed potentials at redox electrodes are related to the relative contributions of exchange currents from various redox couples. For a simple reaction, \( A + e^- \rightleftharpoons B \), the exchange current is related to the currents from the pair of reactions, \( A + e^- \rightleftharpoons B \) and \( B \rightleftharpoons A + e^- \), which are identical at equilibrium. The analogous limitation of a membrane-based ion selective electrode (ISE) is the contribution of an interferent, \( j \), to the potential developed by the analyte, \( i \), in the expression used to quantify the measurements Equation (28):

\[
E = L + \left( \frac{S}{Z} \right) \log a_i + k_{ij}a_j^{z/x} \tag{28}
\]

where \( L \) is a constant; \( S \), the slope which at 25°C ideally is 59 mV; \( z \), the charge of the analyte; \( a_i \), the activity of the analyte; \( a_j \), the activity of the interferent; \( x \), the charge of the interferent; and \( k_{ij} \), the selectivity coefficient. Generally, ISEs (a class that includes the glass pH electrode) provide lower DLs than redox electrodes. They are of limited scope in gas analysis. Here, the analyte must be partitioned from the gas phase into a liquid film that contacts the ISE. Among the analytes for which ISEs can be used are substances that alter the pH of the liquid film and halides.

The use of a pH electrode for the determination of acetic acid in the gas phase was reported. The electrode was contacted to a sodium acetate solution that, in turn, was separated from the sample by a Teflon membrane. The pH changed in response to incursion of acetic acid vapors. A limitation of this approach is that any component of the gaseous sample which shifts the acetate/acetic acid equilibrium will interfere.

Potentiometric measurements of chloride can be made with a silver wire coated with a layer of silver chloride. The potential of this Ag/AgCl electrode is dependent on the activity of chloride ions present. Gaseous HCl can be determined by its dissolution into a basic buffer, thereby forming chloride ion.

A sensor for \( \text{O}_2 \) was developed on the basis of the mixed potential that was developed in conjunction with the corrosion of a cobalt wire. The potential response was from the oxidation of cobalt and the reduction of oxygen on different sites of same electrode. For determining oxygen in air or in the headspace above liquids, sampling was through a gas permeable silicone rubber tubing. The response to the partial pressure of \( \text{O}_2 \) was evaluated using a set of four sensors. A linear plot of \( E \) vs \( \log(P_0) \), where \( P_0 \) is the partial pressure of \( \text{O}_2 \), over the \( P_0 \) range 0.0097–0.94 provided a slope of 112 ± 4 mV (decade)\(^{-1} \). Absolute drift rates of the sensors varied with time. For initial times of 0, 72, and 96 h, the drift rates were 2.1 ± 0.4, 0.78 ± 0.22, and 0.25 ± 0.11 mV h\(^{-1} \), respectively. The drift limits the utility of this sensor for some field applications.

A potentiometric sensor for the determination of tributyl phosphate vapor (TBP) based on a specific charge-transfer interaction with iodine has been reported. The electrode was prepared in a two-step process. The first step involved the electrochemical synthesis of a poly(cyclophosphazenebenzoquinone) (PPBQ) matrix. In the second step, \( \text{I}_2 \) was incorporated into the matrix. Electron-sharing between the \( \text{I}_2 \) and the oxygen on the P=O site of TBP was reported to perturb the electrical properties of PPBQ, which in the absence of TBP are related to the interaction of the \( \text{I}_2 \) with the PPBQ. The potentiometric response reflects a change in the work function, so the system behaves like a FET. A plot of \( E \) vs \( \log(C_{\text{TBP}}) \) is a straight line with a slope of 35.9 mV (decade)\(^{-1} \). The linear range is from 0.27 to 8.8 ppbv TBP.

Overall, solid-state potentiometric devices that provide a response on the basis of work function changes represent an emerging area of electrochemical gas sensors. In many cases, the actual application of this chemistry is to use conductivity changes as the signal, as described in the next section.

### 4.3 Conductivity Sensors

Most sensor designs in this category monitor the conductance change due to a charge-transfer reaction or the interaction of an analyte with a semiconducting material. A complicating factor is that in certain electrolytes (e.g. conducting organic polymers), conductivity can reflect mobility of electrons, ions, or a combination of the two.

Hydrazine sensors are under investigation because it is a highly toxic material at trace levels, and at elevated levels it can promote explosions. In one strategy for its detection, a platform of an electronically conducting polymer, poly(3-hexylthiophene), was deposited onto a quartz substrate by spin coating. The concentration of the gas was related to the increased resistance of the film. The sensor was calibrated to allow the determinations of both dosage of hydrazine (ppb-h) and instantaneous concentration. The dose was determined.
by measuring the change in resistance over a specified time interval; essentially, the data were integrated. The concentration was computed from this value by dividing the dose by the time interval over which a measurement was taken. The resistance varied exponentially with dosages up to 10 ppb-h. This sensitivity allowed 0.1 ppb-h doses and 1 ppb concentrations of hydrazine to be measured. The reproducibility of the calibration curve for 100 sensors was ±20%. Real-time monitoring of a 69-ppb hydrazine stream was measured within 5% of the calibrated value for 10 min, and the response changed less than 5% over an 8-hour period in air. The sensor was shown to be selective through exposure to suspected interferents. These interferents included aniline, dimethylamine, ethylenediamine, and ammonia. The sensor was exposed for 8 h to 16, 80, 80, and 200 ppm-h, respectively, of these compounds; these values are the TLV for these compounds. These exposures yielded signals that corresponded to hydrazine-equivalent doses of 187, 58, 35, and 9 ppb-h, respectively.

An interesting approach to conductivity sensing was to employ Langmuir–Blodgett films of phthalocyanine deposited on a silicon chip containing a gold interdigitated electrode as a platform. By this method, a sensor for the determination of chlorine, bromine, and iodine was developed.\(^{58}\) Included in the design were a micro-heater and a diode for control and monitoring of the sensing film temperature. The primary steps causing the conductivity change were the adsorption of the gas on the film surface and its subsequent diffusion into the film. Evidence for the importance of diffusion into the film was that thickening of the film caused an increase in the signal at the expense of response time. The analyte gas acted as a \(\pi\)-electron acceptor, thereby forming a redox couple. The positive charge that was produced was delocalized over the phthalocyanine ring, which caused an increase of the conductivity. Hence, this was a p-type semiconductor. The sensor had a linear response at room temperature from 20 to 100 ppmv \(\text{Cl}_2\). In order to re-establish the baseline response, the temperature was elevated to a point that resulted in the chlorination of the phthalocyanine ring. It was observed that the maximum signal was attained at different temperatures for each of the analytes. The explanation was that at low temperatures the acceptor holes of doped semiconductors are connected to acceptor sites, which is termed “freeze out”. As the temperature is increased, more holes are ionized; they enter the valence band as free holes. The coulombic field of the adsorbed species makes it more difficult for these temperature-induced holes to escape and produce an increase in conductivity. The higher the electron affinities of species from the gas phase, the higher temperature that is needed for maximum conductance. A possible limitation on the use of this sensor is the irreversible halogenation of the phthalocyanine ring that occurs. Not only will it limit the lifetime but also it establishes the upper limit of the operating temperature of the sensor.

An oxygen sensor employing \(\text{SrTiO}_3\) as the solid electrolyte with a response time fast enough to monitor internal combustion engines has been reported.\(^{56}\) The \(\text{SrTiO}_3\) layer was sputtered onto an \(\text{Al}_2\text{O}_3\) substrate that contained a heater and temperature sensor. The response to oxygen disappeared below 600 °C; moreover, control to ±25 °C was needed for appropriate accuracy.

One of the most promising approaches in sensing is to employ FETs that have coatings for which the work function changes in response to an analyte gas.\(^{49,59,60}\) Formally, the sensing can be by potentiometry or by conductivity. These devices are considered in section 4.4.

### 4.4 Comparison to Related Devices

As mentioned above, FET-based sensors are emerging as important approaches to field measurements of chemical species in gases. One factor driving this field is the compatibility with micromachined assemblies, which allows not only miniaturization but also the deployment of multiple units on the same chip. The latter, in turn, allows the use of chemometric methods such as multivariate analysis to extract information on mixtures, thereby providing enhanced selectivity. An excellent summary of this general topic is present by Domanský et al.\(^{59}\)

Specifically, FET arrays were used to determine mixtures of \(\text{H}_2\) and \(\text{NH}_3\) in air using a combination of \(\text{Pd}\) and polyaniline layers to devise chemically sensitive FETs. The work function change in the presence of the analytes leads to an analytical response function similar to that in potentiometry; that is, the potential is measured vs the logarithm of the concentration of the analyte. Using a related device, but on analytes partitioned into a liquid, \(\text{NH}_3\) and \(\text{SO}_2\) were determined with a pH-sensitive insulated-gate FET.\(^{60}\)

Surface acoustic wave (SAW) devices also are closely related to electrochemical sensors. A SAW device consists of two separate interdigital transducers and two interlocked electrodes on a piezoelectric medium. The first interdigitated transducer produces the SAW by disturbing the piezoelectric medium. The second interdigitated transducer converts the acoustic wave to an electric signal, commonly referred to as a delay line. A coating on the quartz crystal of the piezoelectric device can be deposited in an attempt to obtain selectivity for a given analyte. The adsorption of a species onto the surface or changes in temperature and/or pressure results in a change in the velocity of the wave. This change in velocity is measured as a change in frequency provided that the sensor is part of an oscillator circuit. The relative simplicity of the device is one of the greatest merits for
Employing SAW devices as gas sensors. Because only the surface is used, the device can be printed on a silicon chip. Such production allows for low cost and ease of miniaturization.

One of the major limitations in SAW sensors is the selectivity of the deposited film. Any adsorbed species yields a response. A second SAW device can be employed that has an unmodified surface or one that has been passivated. Here, the difference in response constitutes the analytical signal.

An example of a possible application is a set of SAWs with coatings of tri-substituted triazine derivatives as sensors for chemical warfare agents. A variety of lanthanum coordination compounds were tested for their response to the nerve agent sarin (GB) and the stimulant, dimethyl methylphosphonate (DMMP). The mechanism for adsorption of the test vapors is that the La(III) that is bound to aminopoly-carboxylic acid residues also binds to the oxygen atoms surrounding the phosphorus atom of the analyte vapors. The most effective complex was La(III)2bis(carboxymethyl)aminohexadecanoic acid. A quadratic relationship was observed between the frequency shift and the concentration of the analyte from 1 to 10 ppmv. DLs of 0.1 ppmv were reported. The signal reached 80% of steady-state response in 4 s, and the baseline recovered in 13 s with DMMP as the analyte. The respective times for GB were 8 and 11 s.

Of these related systems, FETs perhaps are the more promising. Selectivity with SAW sensors is established only by adsorption whereas with FET-based devices, adsorption can operate in conjunction with selective chemical reactions such as decomposition.

5 SUMMARY

Electrochemical sensors for field measurement gases are attractive primarily because they have design features that are compatible with mass production by modern micromachining and microelectronics technology. By these methods, inexpensive platforms can be made that combine the necessary instrumentation to develop and transmit signals related to concentration. However, to date, application to chemical sensing has lagged behind physical measurement, e.g. pressure and temperature. As summarized in Arenas et al, a number of electrochemical gas sensors are commercially available, but the list of analytes to which they are applied is limited. In contrast, research on electrochemical sensing has demonstrated that in addition to the small, gaseous species that are commonly determined (O₂, CO, H₂S, CO₂, and NOₓ, for example), electrochemical gas sensors for analytes such as ethanol, various sulfur compounds, phenol, or tributyl phosphate have the response rates, sensitivities, and stabilities to merit widespread application. Devices based on FET designs are especially promising. Finally, an attribute of sensors based on solid electrolytes is that they can be used in harsh environments, including the monitoring of gases at high temperature.

Volatile organic compounds (VOCs) exist in the vapor phase in ambient air at partial pressures ranging from less than 1 part per billion to a few parts per million. Some of them are toxic and potentially harmful to the environment and to human health. The threshold concentrations at which individual compounds become harmful is often not well defined, and less is known about mixtures. Accurate assessment of health risk requires analytical methods that are accurate, affordable, convenient, fast, and sensitive enough to detect each compound at a concentration below the threshold of harmful effect. The usual approach to identification and quantitation of them has been to collect samples and submit them to laboratory analysis. United States Environmental Protection Agency (USEPA) Method TO-14 is a standard procedure for analyzing a group of 41 potentially harmful nonpolar and semipolar organic compounds, which is in widespread use and has been found to detect and measure target compounds reliably under most conditions. However, more rapid delivery of data is often needed, and samples can deteriorate during storage pending analysis. Alternative analytical methods that produce immediate data are needed. Analysis of samples at the time and place of collection has seldom been done because of the lack of suitable equipment and the vicissitudes of operating it under field conditions. Portable or field-deployable gas chromatographs (PGCs) have, with cause, been regarded as less accurate than laboratory equipment, and a perception remains that analyses done in the field are less useful than those done in the laboratory. In fact, laboratory- and field-based analyses each have inherent advantages and disadvantages, and using them together can finesse the disadvantages of both. A high-speed gas chromatograph (GC) using a time-of-flight mass spectrometer (TOFMS) detector can mitigate the problem of delayed data.
1 INTRODUCTION

VOCs exist in the vapor phase in ambient air at partial pressures ranging from less than 1 part per billion (ppb) to a few parts per million (ppm). Some of them originate from natural processes, such as plant and animal metabolism, but most come from chemical manufacturing, combustion, and related processes. Some VOCs are toxic and potentially harmful to the environment and to human health. The threshold concentrations at which individual compounds become harmful is often not well defined, and less is known about mixtures. Accurate assessment of health risk requires analytical methods that are accurate, affordable, convenient, fast, and sensitive enough to detect each compound at a concentration below the threshold of harmful effect. There are many VOCs in air at trace concentrations, and the more sensitive the analytical method, the greater is the number that will be detected. The usual approach to their identification and quantitation has been to collect samples and submit them to laboratory analysis. A typical procedure includes (1) collection of whole air samples in passivated canisters or separation of VOCs from air on a sorbent cartridge, (2) delivery of samples for analysis, either by passing whole air from a canister sample through a cryogenic trap to separate VOCs from the air matrix or by thermal desorption of VOCs from a cartridge into an inert gas stream which then passes through a cryogenic trap, followed by (3) vaporization from the cryotrap into the carrier stream of a GC which may then be detected. The usual approach to their identification and quantitation has been to collect samples and submit them to laboratory analysis. A typical procedure includes (1) collection of whole air samples in passivated canisters or separation of VOCs from air on a sorbent cartridge, (2) delivery of samples for analysis, either by passing whole air from a canister sample through a cryogenic trap to separate VOCs from the air matrix or by thermal desorption of VOCs from a cartridge into an inert gas stream which then passes through a cryogenic trap, followed by (3) vaporization from the cryotrap into the carrier stream of a GC which may then be detected.

2 CHARACTERISTICS OF LABORATORY- AND FIELD-BASED ANALYSES

2.1 Advantages of Laboratory-based Operation

Laboratory instruments are usually near state-of-the-art and are operated by competent personnel in a sheltered environment, which inspires confidence in their reliability. Because the operating environment is stable, detection limits (DLs) can readily be minimized. It is desirable to operate at maximum sensitivity for several reasons: (1) it may not be known at what level the harmful effect of a compound becomes significant; (2) if the method is continuously detecting trace levels, there is a positive indication of proper function, which is not the case if nothing at all is reported until some threshold concentration is exceeded; (3) there are worldwide ambient background concentrations of certain compounds, e.g. tetra-chloromethane (CAS 56-23-5) at ~0.13 ppb, which indicate proper function if the method is sensitive enough.

2.2 Disadvantages of Laboratory-based Operation

Large monitoring projects produce backlogs of samples which endure long periods of storage, during which samples may deteriorate, especially if highly reactive or corrosive compounds were collected. A sample analyzed accurately in the laboratory may no longer be the sample that was collected in the field. Although sample integrity during storage in passivated canisters has been demonstrated in the absence of highly reactive compounds, artifact formation can be caused, for example, by HCl. Samples are analyzed one at a time, and analyses can be delayed by equipment malfunction. Meanwhile, sample collection is blind, guided only by theoretical inferences and human olfaction, and canisters or cartridges awaiting analysis are not available for use. A faster way to obtain data is needed, one which can point to places which need more thorough investigation and also provide timely estimate of risk to field personnel.

2.3 Advantages of Field-based Operation

Portable instruments, which analyze VOCs in ambient air without storing or preconcentrating samples, can minimize sampling errors and produce data in near real-time, so that sampling protocols can be modified to use results as they are obtained. Sample “storage” is vanishingly brief, so that there is little or no time for samples to become corrupt. Since PGCs are more easily transported than large numbers of sampling devices, they can produce larger volumes of data at lower cost. Also, when analysis is performed on-site, data are immediately available, and more thorough investigation can be done faster at less cost.
2.4 Disadvantages of Field-based Operation

Many of the disadvantages of on-site analysis arise from the instability of field environments. Sunshine or rain falling directly on a PGC can wreak havoc and perhaps terminate function. GCs in general, whether laboratory or portable, cannot perform while subjected to significant fluctuations in ambient temperature, since that affects both column temperature and detector sensitivity. Every field operator has experienced the frustration of seeing careful PGC placement foiled by inclement weather and fervently wished for costlier, heavier, bulkier but more robust equipment. There are other disadvantages: many PGC columns are isothermal, so they are not able to analyze as many compounds per run as temperature-programmed laboratory instruments. Design compromises intended to reduce cost and enhance portability and the rate of sample throughput can limit performance. The short columns used to minimize analysis times sacrifice resolution for speed. PGCs can be calibrated for only the limited number of compounds which their (usually) specific detectors can see at low parts per billion levels, and they almost always rely heavily on retention time for compound identification. Finally, they require skilled operators. For these reasons, laboratory-based analysis remains more popular, although it must be conceded that data from good analyses of bad samples can be as useless as data from bad analyses of good samples.

2.5 Use of Laboratory- and Field-based Analysis Together

It has become widely appreciated that the integrity of sample-handling procedures, no matter how sedulously designed, cannot be taken for granted. On-site and laboratory-based analyses can be used together so that their respective advantages and disadvantages complement each other. PGCs can be useful for showing where intensive sampling is needed, so that laboratory-based analysis can be applied with maximum efficiency, and they can validate data from laboratory analyses because their data quality is not affected by sample degradation during storage. If laboratory and field methods consistently produce similar results, then probably both are correct. If they differ, that difference may indicate what went wrong and what can be done about it.

3 DETECTORS

A variety of detectors are available for PGC. There are two kinds: universal detectors respond to almost everything that elutes from the column whereas selective detectors respond to certain classes of compounds while ignoring all others.

3.1 Universal Detectors

Universal detectors are those which respond to any change in the composition of the carrier stream. The thermal conductivity detector (TCD) consists of a pair of filaments or thermistors which form half of a Wheatstone bridge. The carrier stream and a reference stream flow past each of them at the same rate. When both streams are identical, the filaments or thermistors are cooled at the same rate, the bridge stays in balance and the voltage across it is zero. Any change in the thermal conductivity of either stream unbalances the bridge, resulting in a net voltage which is directed to a recording device. Obviously stable flow rates are critical to proper function. Since the thermal conductivity of a gas consists of a combination of translational, rotational, and vibrational energy modes, the introduction of molecules other than the carrier gas will change it. Among commonly used carrier gases helium is monatomic, having only translational energy, so any molecular species eluting in a helium carrier stream must produce a response. TCDs are not very sensitive, although Hewlett-Packard/Microsensor Technology (MTI) produces chromatographs with a micromachined TCD which has a volume of 240 nL and can detect airborne vapors at concentrations as low as ~1 ppm. An instrument of that sensitivity is primarily useful for industrial hygiene application, and preconcentration of samples by three orders of magnitude is necessary to use it for ambient air analysis.

A flame ionization detector (FID) feeds the carrier stream into a hydrogen–air flame in which eluents are burned, producing ions to be collected on electrodes. The resulting current is amplified and sent to a detector. A moderate concentration of water in the carrier stream will not be detected, since it is the principal product of the flame. Other substances that do not burn are detectable only to the extent that they ionize. The response to a compound is roughly proportional to the number of its carbon atoms. FIDs are more sensitive than TCDs but are not the most sensitive detectors. They are frequently used without chromatography as a “total hydrocarbon” monitor. Their relative insensitivity and their need for hydrogen and air supply limit their use in the field, although some commercially available PGCs are equipped with them.

An argon ionization detector (AID) ionizes atoms of argon carrier gas with a radioactive source. The argon ions then react with analyte molecules to ionize them, after which they are collected on electrodes. Because of the relatively high energy of the process (11.7 eV), most compounds respond. AIDs are relatively sensitive and are useful for analysis of highly volatile “light end” compounds which, having fewer carbon atoms to oxidize,
are least detectable with an FID, and, having fewer vibrational/rotational modes, are least detectable with a TCD. Since there are fewer isomers of low-molecular-weight compounds (butane and smaller), all of them can be separated with even the short columns used in PGCs. For larger molecules, it becomes increasingly difficult to distinguish toxic analytes from the multitude of relatively innocuous background compounds that co-elute.

A high-energy photoionization detector (PID) ionizes eluting compounds with an 11.7-eV ultraviolet lamp. It is a universal detector for the same reason that an AID is universal, and its performance is similar. Its function is analogous to that of lower energy PIDs as described below.

### 3.2 Selective Detectors

PGCs generally use short columns to facilitate short analysis times, so their chromatographic resolution is low, but even laboratory GCs with full-length columns cannot resolve all the trace-level (<5 ppb) compounds in an air sample. Typically, when a sample containing trace levels is analyzed on a temperature-programmed column using a mass spectrometer detector, about 200 peaks appear, each containing 3–5 compounds that can be recognized and an unknown number of others which escape tedious scrutiny. A detector that responds only to compounds of interest is clearly useful. Selective detectors respond to specific classes of compounds but not to other compounds that co-elute with them.

The **PID** consists of an ultraviolet lamp which irradiates the carrier stream. Eluent molecules having ionization potentials lower than the radiation energy are ionized to produce an ion current. Detector selectivity is determined by radiation energy. High-energy lamps (11.7 eV) are virtually universal detectors. Lower energy lamps (10.6 eV and below) ionize many double-bonded compounds, such as aromatic hydrocarbons and olefins, but not saturated compounds such as hydrocarbons and halocarbons. Toxic and carcinogenic compounds with double bonds are readily detected by low-energy PIDs. However, not all low-energy PIDs are alike. Some of them use medium-pressure lamps, others use low-pressure lamps and both have advantages. Medium-pressure lamps are physically more robust than low-pressure lamps and emit a relatively broad band of wavelengths. They run hot, so they can be used with heated columns. Low-pressure lamps emit an extremely narrow resonance fluorescence line with intensity far exceeding that of a medium-pressure lamp. Detectors equipped with low-pressure lamps are extremely sensitive. The disadvantage is that heating them causes the emission line to broaden and lose intensity. As a result, PIDs based on low-pressure lamps are used for isothermal analysis of volatile compounds. They are generally less robust than medium-pressure lamps, and their service life is shorter. The intensity of light emitted by low-pressure lamps is so great that second photon absorptions cause ionization of compounds with ionization potentials slightly above lamp energy. A low-pressure PID-equipped PGC can be calibrated for compounds with higher ionization potentials, but it is advisable not to do that when analyzing trace levels in ambient air. For example, tetrachloromethane can be detected at concentrations of 1 ppm and above, but it elutes near benzene (CAS 71-43-2) on many columns. Benzene, being formed in all manner of combustion processes, is ubiquitous and detectable at sub-parts per billion concentrations, so it could be erroneously identified by a microprocessor as tetrachloromethane at a concentration high enough to precipitate panic. The development of PID detectors has been reviewed.\(^{(1)}\)

The **surface acoustic wave** (SAW) detector is based on the ability of molecules adsorbed on a piezoelectric crystal to change the velocity of a sound wave propagated along its surface. Vibration by the sound wave causes the crystal to generate an electric current which can be amplified and recorded. Deposition of polymers on the surface can alter the velocity at which sound is propagated so as to tune the crystal to respond to three or four compounds in preference to others that might co-elute with them. SAW detectors for a variety of compounds are under development.\(^{(2)}\) In general they ignore all but very high concentrations of coeluting compounds.

The **electron capture detector** (ECD) uses a radioactive source to ionize the carrier gas, producing an electron current which is continuously monitored. When a compound with high electron affinity arrives in the detector it captures electrons, and the resulting decrease in electron current is detected. ECDs are extremely sensitive to perhalo compounds such as tetrachloromethane, tetrachloroethylene (CAS 127-18-4) and hexachlorobutadiene (CAS 87-68-3). They are less sensitive to compounds having fewer halogens. Since they are highly selective, they are potentially useful for detection of any compounds with high electron affinity.

**Mass spectrometers** function as both universal and specific GC detectors. They have not been used much in portable instruments because of size and cost, although field-deployable gas chromatograph/mass spectrometer (GC/MS) instruments are now commercially available. The use of mass spectrometers as GC detectors is discussed in section 7.3.

A variety of other specific detectors, including flame photometric, electrolytic conductivity, far-ultraviolet and thermionic ionization, can be used with some of the commercially available PGCs.
4 COMMERCIALY AVAILABLE DEPLOYABLE GAS CHROMATOGRAPHS

Early PGCs were crude, insensitive devices, hardly capable of analyzing anything of significance. They typically featured syringe injection onto a packed column leading to a TCD connected to a galvanometer or an external strip-chart recorder. When the Photovac (PVK) 10A10 appeared, it was claimed to detect less than 1 ppb of benzene in 1 mL of air. It differed from predecessors only in that it had a low-pressure PID. Its simple design was followed by instruments from PVK and other vendors which automatically collect samples and inject them into capillary GC columns and use many different detectors. Data are processed by on-board microprocessor-based algorithms. Such innovations have made the task of on-site analysis more practical and more accurate for both identification and quantitation.

4.1 Characteristics and Capabilities

Field-based analytical instruments can be characterized as portable or deployable. Truly portable instruments are virtually self-contained. They are battery powered and have an internal carrier gas supply. An operator can lift the instrument with one hand, not necessarily while in use, although some PGCs are almost capable of hand-held operation. A field-deployable instrument requires line power and usually an external carrier gas supply also. It may be too heavy for a single operator to shift conveniently. Some are laboratory instruments that have been reduced in size for convenience and hardened for transport. Some currently and potentially available portable GCs are listed in Table 1 and field-deployable GCs are listed in Table 2.

4.2 Evolutionary Trends in Commercially Available Instrumentation

There is considerable variety in technical detail among PGCs. The current market is reminiscent of the early days of the automobile when steam power and battery power vied with internal combustion power rolling on tires, solid or fragile, along roads that were scarcely passable, burning fuel that was marginally available. Evolution of the automobile subsequently converged upon the most practical technical designs, and PGCs will do likewise. At present, emulation of data from concurrent collocated laboratory-analyzed samples is prominent among criteria for evaluation of PGCs. In future, it may become more common for laboratory analyses to be judged by how well they emulate data produced by field-deployable instruments, since they analyze fresh samples.

5 FIELD EVALUATION STUDIES

Beginning in the mid-1980s, the USEPA conducted a series of field evaluation studies of PGCs. The study design has evolved from early attempts to determine

whether the PGC could detect anything at all toward a systematic comparison of PGC data with data obtained by other means. The earliest studies were conducted in the southern USA at various locations from Texas to Virginia. Gradually USEPA Method TO-14 has become the usual reference standard method for comparison with PGC data. Some of the studies are described below.

### 5.1 Vilnius, Lithuania

In May and June 1989, two PVK 10S70 PGCs were operated at a roadside site near Vilnius in a joint study of automobile exhaust by the USEPA and the Voeikov Main Geophysical Observatory in Leningrad. Whole air samples were also collected in passivated canisters which were returned to the USA and analyzed by Method TO-14. Time-integrated canister samples were collected over a 2-h period, while the PGC data were periodic grab samples taken during that time. Not enough canisters could be transported to dedicate part of them to simultaneous grab sampling with PGCs. Although not identical, the PGC results were in close agreement with each other and in substantial agreement with TO-14 data.\(^8\)

![Figure 1](image_url) **Figure 1** Concentrations of benzene, trichloroethylene (CAS 79-01-6), toluene, chlorobenzene (CAS 108-90-7), ethylbenzene (CAS 100-41-4), m- and p-xylene (CAS 108-38-3 and CAS 106-42-3) and o-xylene (CAS 95-47-6) found at Grantham Lane.

### 5.2 Northern Delaware

Also in 1989, collocated canister grab samples were taken simultaneously with PVK 10S70 samples at various industrial sites in Northern Delaware. Figures 1–4 show progressively increasing agreement between the two methods as concentrations increase.\(^7\)
5.3 Crosby, Texas

In January 1992, six commercially available PGCs were evaluated at a Superfund site during start-up of bioremediation. This site was an abandoned and flooded gravel pit into which refinery waste had been dumped. Floating organic material on the surface of the pond had been burned periodically, leaving a layer of about 4 m of organic sludge overlain by a like depth of water that was clean enough to support some aquatic life, but volatile solvents were leaching out of the sludge into groundwater and threatening nearby water wells. Bioremediation was done by vigorous mixing of water and sludge while oxygenating and fertilizing to encourage some of the ambient bacteria. In a pilot study, the air used to supply oxygen had purged out substantial amounts of VOCs which led to high airborne concentrations in the surrounding area. During actual bioremediation, pure oxygen was used instead of air, and there was very little airborne contamination. The PGCs were located near the perimeter of the pond, where concentrations of VOCs proved to be slightly above ambient background levels. Collocated grab samples were collected in Summa-polished canisters during PGC sampling. They were analyzed by Method TO-14 using a MSD and served as reference standards to assess the accuracy of data reported by the PGCs.

The PGCs included a PVK 10S Plus with a 10.6-eV PID, Microsensor Systems 301 with a SAW, STX Scentograph with an 11.7-eV AID, HNU Model 311 with a 10.2-eV PID and SRI 8610 with a 10.2-eV PID and an ELCD. A PVK 10S70 owned by the USEPA was also used. All units were operated inside a shed where the temperature was maintained at about 21 °C. It was located 6 m laterally and 4 m above the edge of the pond. Each unit used its own sample pump to import outside air through 1/8 in o.d. stainless-steel tubing. Calibration checks were performed periodically using mixtures prepared by dynamic dilution of commercial standards and stored in 6-L Summa-polished canisters. Grab samples were collected by opening the valve of an evacuated canister while holding it within 75 cm of the gathered ends of the sampling tubes while samples were collected. Canister samples were analyzed by Method TO-14 using gas chromatography with mass selective detection (GC/MSD). Canister data were taken to indicate true identities and concentrations of the compounds present. DLs for the PGCs, shown in Table 3, were calculated using data acquired during field calibrations. They were not as low as DLs determined under laboratory conditions but were typical of what can be expected under field conditions. Figures 5 and 6 contrast data from two grab samples with corresponding PGC data. Labeled vertical bars indicate PGC data and

canister data are shown as horizontal lines. Analyte levels were near the DLs in Table 3, and the agreement between PGCs was close enough to show that several of them could provide reasonable estimates of the compounds for which they were calibrated. A detailed report of the study has been published.\(^{(14)}\)

5.4 Bayamón, Puerto Rico

During June 1993, a field study was conducted near San Juan to compare data produced by two PGCs with data from samples which were collected simultaneously in 6-L Summa-polished canisters and analyzed by Method
TO-14. They were the CMS Series 2000 Field MiniCAMS with an FID and a solid-sorbent preconcentrator, and the HNU Model 311 with a PID which periodically sampled the continuously pumped air stream by diverting the contents of a sample loop. In this study, each commercial instrument was operated by a factory representative, and vendors were responsible for calibration, maintenance, and troubleshooting their own equipment. The site was at a monitoring station operated by the Junta de Calidad Ambiental (JCA) (Environmental Quality Board) at the jail in Bayamón, within the San Juan Metropolitan Area and downwind of the Cataño industrial area. JCA had two small shelters with air conditioning and electric power. The PGC operators collaborated to rent a recreational vehicle to which electric power from a JCA building was connected so it could be used as a mobile laboratory during the study. A schematic of the area around the site is shown in Figure 7. Ambient concentrations were lower than expected. Canister samples of ambient air collected during the study were analyzed by Method TO-14 using GC/MSD. Canisters were filled by holding the valve within 20 cm of the group of PGC inlets and opening it just far enough to fill the canister while the PGCs were sampling.

Occasionally, each instrument analyzed an audit standard which had been certified before the study by GC with FID and ECD. After the study it was analyzed again by GC/MSD. There was little change in the audit standard between analyses before and after the study. The standards included all 41 compounds on the TO-14 target list, although the PGCs were calibrated for only four of them. Each PGC performed several analyses of the audit standard, and field audit data were in close agreement with laboratory analyses for both PGCs.

PGCs were calibrated for benzene, toluene (CAS 108-88-3), m- and p-xylene (CAS 108-38-3 and CAS 106-42-3) and o-xylene (CAS 95-47-6). Agreement between PGC and canister data, although not exact, was close. Concentrations of analytes varied between 0 and 25 ppb. An understanding of how well the methods agreed can

Figure 8 Average values (horizontal lines) and standard deviations (SDs) (vertical bars) of absolute values of differences between canister/TO-14 data and corresponding PGC data in the Bayamón Cárcel field study. (Reproduced by permission of InfoScience Services Corporation.)

be obtained by averaging the absolute values of the differences between the PGC and TO-14 results for each compound for all comparison runs. Average absolute differences are represented by the elevations of the thick horizontal lines in Figure 8. The SD of the absolute values of the differences is shown by the bar extending above and below the line. Differences were finite, real, and relatively small, except at lowest concentrations. The averages are not much larger than their SDs, which suggests that the differences are essentially random and do not contain a large component of systematic error. The differences, averaged without taking absolute values

Figure 9 Average values of differences between canister/TO-14 data and corresponding PGC data in the Bayamón Cárcel field study. (Reproduced by permission of InfoScience Services Corporation.)

so that positive and negative values tend to cancel each other, are shown in Figure 9. A slight negative bias is apparent.

If the peak recognition algorithm of a PGC has retention time windows set too wide, then interferences become more likely. If the variation in retention time for a certain compound is substantially larger than for the analytes eluting before and after it, then intermittent misidentification of an interfering compound could be the cause. The retention time stabilities of each analyte on each PGC were evaluated by comparing the SD of all retention times for each compound with the mean

Figure 10 Average retention times and SDs of retention times for PGCs used in the Bayamón Cárcel field study. (Reproduced by permission of InfoScience Services Corporation.)
retention time of that compound. Retention times are contrasted with SDs of retention times in Figure 10. The width of the tiny rectangular boxes at the ends of the bars represents the SD of retention times, which were small enough (invisible in most cases) to suggest that chromatographic conditions were stable during the study, and that the peak identification algorithms were finding only a single compound within each peak identification window. A detailed report of the study has been published.\(^{(15)}\)

5.5 Lawrence, Kansas

In August 1995 a field study was conducted on the intramural playing fields of the University of Kansas. PGC vendors were invited to participate at their own expense. An artificial plume of analytes was used, so that control over identities and concentrations of analytes could be exercised, adequate use could be made of audit standards and field blanks, and as many participants as chose to attend could be accommodated. The six participants in this study included four PGC vendors, a contractor operating the reference Canister/Method TO-14 method, and a contractor operating a mobile triple quadrupole mass spectrometer (TAGA) mounted on a bus. The PGCs were the PVK 10S Plus, with a low-pressure 10.6-eV PID, the STX Scentograph with an 11.7-eV AID, the MTI M200 and the MSA-Baseline (MSA) Ekho-M. The MTI was operated by Louisiana State University Institute for Environmental Studies (LSU). It had a microbore column and a micromachined 240-nL TCD and used a separate preconcentrator. The Ekho-M chromatograph originated in the Siberian Department of the Russian Academy of Sciences as an explosives detector and was under development as an air monitor by MSA. Its column consisted of a hexagonal bundle of 1000 parallel microbore capillaries, each 20 cm in length. The bundle was 2 mm in diameter. This unique design permitted analysis of a relatively large sample without overloading the column. An AID was used.

5.6 Reference Method

Reference samples were collected in Summa-polished 6-L canisters. A mechanical flow controller was used to fill canisters at a uniform rate during the sample collection period. In some cases, two canisters were filled on either side of the PGCs to check uniformity of the plume. In other cases, especially during turbulence, one canister was filled at the inlet of each PGC. Southwest Research Institute (SWR) analyzed the canister samples by Method TO-14. The TAGA was placed downwind of the sampling devices to confirm the presence of the plume before sampling began.

5.7 Source Generator

Instead of sampling near an industrial or hazardous waste site, a source generator was used to create a plume of airborne vapors at a pristine site. The plume was generated by using a paint sprayer to project a fine spray of a solvent mixture out the top of a metal tube approximately 15 cm in diameter and 2 m tall. Samples were collected at least 70 m downwind, as shown in Figure 11, where it was expected that mixing of vapors with air would be reasonably thorough. Plume composition was changed between sampling periods.

5.8 Procedure

Participants were required to calibrate their own instruments. PGC sampling began after the TAGA confirmed the arrival of the plume. Since the PGCs had sampling periods of different lengths, starting times were staggered to coincide their mid-points.

5.9 Audit Standards

Audit standards at nominal concentrations of 2.5, 7.5, 15, 25 and 40 ppb of each compound were prepared by dynamic dilution of a commercially prepared, nominally 10 ppm mixture of TO-14 target compounds in nitrogen. Each PGC operator was required, without knowing the concentration in the canister, to analyze at least one audit standard at each level. Data from these analyses were plotted to determine linearity of response and accuracy of calibration. Audit standards were also
submitted to analysis by SWR. The PGCs which relied on preconcentration (LSU, MSA, STX) showed more scatter than the one which did not (PVK). Results for all compounds analyzed by all PGCs and the reference method were summarized in terms of averaged correlation coefficients. Figure 12 displays averages of the correlation coefficient values for scatter plots of all compounds reported by each method. The closer a value approaches unity, the higher the degree of correlation and the better the fit to linear plots. Data produced by MTI and MSA were more scattered than data produced by PVK and STX or by the SWR canister/TO-14 reference method. That difference is consistent with the greater experience of PVK and STX, and the laboratory basis of the analyses performed by SWR. Also, PVK, having an exceptionally sensitive detector, does not preconcentrate samples. Although the precision may be slightly impaired by the additional preconcentration step, it appears to be more affected by operator experience. Analysis of audit standards was the most successful part of the study. There was little to choose between PVK, STX, and SWR with regard to linearity of scatter plots. The lower correlation coefficients registered by MTI and MSA reflect the considerably shorter time that each of them has practised sample collection by preconcentration. They will undoubtedly profit from further experience.

5.10 Plume Sampling

Inclement weather disrupted much of the study. Surface wind varied capriciously, thunderstorms appeared at intervals, and temperatures above 32°C prevailed between storms. As a result, the reference method often did not function properly. Canister grab samples are no more effective than PGCs for characterizing an unmixed plume. This outcome was disappointing, but not surprising. A study based on use of a plume generator must depend on fair weather, which was forthcoming only sporadically. Analyses performed during periods of relative calm and consistent wind velocity produced data that generally resembled those shown in Figure 13. Analyses done during turbulent weather showed no agreement between portable chromatographs and no agreement with the reference method, as shown in Figure 14. PGC retention time stabilities for o-xylene (CAS 95-47-6) are illustrated in Figure 15. PVK retention times were more variable because the operator changed the carrier flow rate before recalibration. When SDs of retention times were calculated separately for runs pertaining to each calibration, they were significantly smaller, and the average of those SDs, displayed in Figure 16, is labeled “10S Plus Re-averaged”. Detailed reports of the study have been published.

6 Conduct of Field Evaluation Studies

6.1 Organization
A field evaluation study needs a coordinator to organize the efforts of participants and make necessary arrangements. It requires cooperation among a group of persons which, at minimum, must approximate the largest number of operations to be carried out simultaneously. In field studies where multiple PGCs are compared, the number of them which can be evaluated is limited by the number of operators, which is limited in turn by available shelter. Extensive on-the-spot assistance by vendor technical representatives has proven crucial to the success of field comparison studies. It is best to have PGC vendors participate at their own expense using their own instruments and performing their own calibrations. Vendors gain valuable experience from participation in field studies. They learn how their instruments perform in a field environment, and they find out what competitors can do.

6.2 Site Selection
An ideal site for a comparison study would be located near a source of elevated concentrations of compounds that the participating PGCs can detect, such as high traffic areas, industrial complexes, and hazardous waste sites. Sponsorship by a local property owner or government authority is necessary. Issues of jurisdiction and security for the participants must be satisfactorily managed.

6.3 Existing Sources
A facility manager who suspects that his site emits significant quantities of toxic VOCs will be reluctant to entertain people who are bent on proving it. Neighbors, provided their own houses are in order, may be less reluctant. For a field study, several important vapors should be present at concentrations in the range 5–50 ppb. Such ideal conditions are difficult to find.

6.4 Artificial Sources
An alternative to finding a site with adequate amenities and suitably polluted air is to use a pristine site and pollute it temporarily with a source generator. The advantages are (1) knowing which analytes will be present, (2) being able to control their concentrations, and (3) being exposed to them only during sampling and not at other times. The disadvantages are that there are relatively few compounds which are suitably volatile and sufficiently innocuous to be released into the air at high concentrations, and the forbidden compounds are precisely those which are most interesting.

6.5 Reference Analytical Method
Concurrent collocated grab samples can be collected by holding the inlet valve of the canister adjacent to the PGC intake tubes and opening it slightly so that the canister fills completely during the sampling period of the PGCs. If the sample collection intervals of PGCs differ, then PGC start times can be staggered so that the mid-points of all the sampling periods coincide. A mechanical flow
controller can be used to assure a constant sampling rate for the canister during the longest sampling period. Having all PGCs and the reference method sample air from a common manifold through which air is drawn by a pump could be advantageous, but different PGCs sample at different flow rates during different intervals, so nothing can prevent confusion if concentrations change during a sampling period.

6.6 Audit Standards

Audit standards can be provided in canisters for analysis by each PGC at several concentrations in the 0–50 ppb range. Each participant should analyze each concentration as many times as possible, and the standards should be laboratory-analyzed before and after the study. Accuracy and linearity of response can be assessed from audit data independent of meteorological interferences. Audit standard data reveal problems with instrument and operator performance, including calibration errors, systematic sample collection errors, and poor precision, and they guarantee useful data in spite of bad weather.

6.7 Data Reporting

The coordinator is responsible for receiving data from participants and processing them. The volume of data will be large, and data reporting should be planned in advance. Where possible, data should be submitted as computer files in specified format. Otherwise, they will arrive in a variety of formats. Almost anything is possible, from numbers scribbled on paper towels to spreadsheet files on disk, and the organizational schemes of those files will be limited only by the fertile imaginations of participants. Each will be rational and no two alike. A prudent coordinator will impose uniformity on data reports in advance. Otherwise, unlimited time will be spent teasing order out of chaos. Data from the reference method will not be available until a month or two later. When it comes, the coordinator must try to remember what was done 2 months earlier while matching reference data with PGC data. Having aged 2 months will not render him omniscient.

7 HIGH-SPEED LABORATORY ANALYSIS ALONG WITH FIELD-BASED ANALYSIS

Laboratory GCs using fused-silica capillary columns have defined the state of the art for airborne VOC analysis. They have generally been optimized for maximum chromatographic resolution, so that chromatograms run 30–80 min and display as many peaks as possible. Sample delivery to the instrument, cooling the GC oven between runs, and data processing also take time. A faster method could enhance the usefulness of laboratory data which would not be immediately available but would appear much sooner, and might be partially reported to the field crew while still on-site. Sample storage would be minimized. Occasional system failures further delay data. A reference standard method that produced laboratory data as fast as PGCs would be valuable for evaluation studies and could form part of a dual analytical method more powerful than its laboratory- and field-based components.

7.1 High-speed Gas Chromatography

Gas chromatography is the most widely used analytical technique for analysis of VOCs in ambient air.\(^{(18)}\) Starting in 1965, reports began to appear about high-speed or fast gas chromatography (FGC).\(^{(19–25)}\) Recently, the design and application of a FGC system to air monitoring has been reported.\(^{(26–29)}\) Even specific detectors may not completely eliminate interferences. The duration of a chromatogram can be drastically reduced by increasing column head pressure to speed up carrier velocity (100–200 cm s\(^{-1}\)) through a short column. Shortening columns and increasing the carrier flow rate reduces the resolution but need not proportionally decrease the separation. Injecting the sample in a narrower bandwidth (<10 ms) produces peaks which are narrower and therefore better separated at the same resolution.\(^{(27,28,30–32)}\) On the other hand, many GC detectors cannot collect data rapidly enough to describe such narrow peaks accurately, so special fast detectors must be used. Also, increasing carrier gas velocity reduces GC column capacity and limits sample size. On the other hand, narrower peaks are taller and thus more detectable if the detector can trace them accurately. The difficulties of reproducibly performing narrow bandwidth injections and detecting narrow peaks have long inhibited use of FGC, but recently, a reliable narrow bandwidth injection system has been marketed by Chromatofast Inc., and various kinds of fast detectors have become available. Chromatograms of maximum duration are no longer necessarily optimal. Indeed, lengthening chromatograms to maximize chromatographic resolution and minimize interferences between analytes and background hydrocarbons is futile.

7.2 High-speed Mass Spectrometry

By most criteria, mass spectrometers would be ideal GC detectors. They are both universal and specific. In most cases they can identify analytes unequivocally, even in the presence of interferences. Their output can be searched using mass spectral databases, and they can be used for quantitative analysis. The problem has always been that mass spectrometers were too slow to be compatible with
capillary GCs. Mass spectral scans, until recently, could be done perhaps three times per second without undue sacrifice of mass spectral resolution, unless the scan range was narrow. Collimation to focus and improve mass spectral resolution wasted much of the ion beam and curtailed response. Early-eluting capillary GC peaks are typically about 1 s wide and could not be adequately traced by the three data points that a mass spectrometer scanning at maximum practical speed could produce. It was necessary to sacrifice chromatographic resolution in order to “see” early peaks. The marriage of these two powerful analytical techniques, although successful, was not a happy one.

Recently, Leco Corporation has marketed the Pegasus II, a TOFMS that was originally designed by Holland and co-workers specifically as a detector for FGC. A schematic diagram of the high-speed TOFMS is shown in Figure 17. It can acquire and record up to 500 mass spectra per second. Use of prototype high-speed TOFMSs has been demonstrated for a variety of analytical applications. A TOFMS differs from other mass spectrometers in that it does not “scan”. Instead, the ions are ejected from the ion source periodically by a positive pulse which projects them along the axis of a “drift tube”. Instead of a series of tiny collimation apertures, they pass through a hole about 2 cm in diameter at the entrance to the drift tube. At the far end they encounter a positive electrical field or “reflectron” which reflects them back at a small angle toward an array detector located near the ion source. Ions having more or less than average velocities along the axis of the drift tube penetrate the reflectron to greater or lesser depths, respectively, so that all ions of the same mass emerge from the reflectron at the same time with their thermal energy spread minimized and their mass spectral resolution enhanced. Ions are pulsed from the ion source at a constant rate of 5 kHz, and the resulting mass spectra are averaged before being written to disk at an operator-selected rate up to 500 Hz. Each mass spectrum written to disk is an average of 10 or more individual spectra, depending on how fast they are recorded. The Pegasus II is fast enough to cope with the output of any FGC. Since all the ions forming each mass spectrum are ejected from the ion source simultaneously, the individual mass spectra are not biased by changes in concentration in the ion source which occur during the time taken by an ordinary mass spectral scan. Averaged spectra recorded at more than 30 Hz are practically free from bias, and peak deconvolution, being much simplified, can be done with simple algorithms, which makes it possible to process GC/MS data in real time.

Occasionally TOFMSs have been adapted to perform as GC detectors without benefit of supporting software. The volume of raw data produced by FGC coupled with a TOFMS is enormous. To process manually data acquired in 1 day into publishable information can take months. The Pegasus II incorporates software which controls the GC and TOFMS system, records and processes data, and compiles reports. Data are written to disk in real time and data processing takes about as long as acquisition and may be done concurrently.

7.3 High-speed Gas Chromatography/Mass Spectrometry Analysis

The combination of a modified Chromatofast injection accessory with a Varian 3400 high-speed GC and a Leco Pegasus II TOFMS has been used to demonstrate rapid analysis of whole air grab samples collected in 6-L passivated canisters by a procedure analogous to USEPA Method TO-14. The Chromatofast withdrew 3 mL min⁻¹ of air from a sample stream. During a period of 40 s, 2 mL of air were passed through the cryotrap. Then the trap was heated by capacitive discharge to inject the sample in a narrow bandwidth (<10 ms) on to a 12 m × 0.25 mm column coated with 1.4 µm of DB-624. The turn-around time between injections was less than 10 min. The GC oven was programmed from 50 to 170 °C at 35 °C min⁻¹. About 200 s were required for all compounds on the TO-14 target list to elute. Individual ion chromatograms for seven ions from the same chromatogram are shown in Figure 18.

8 CONCLUSION

8.1 Present State of Field-based Analysis

On-site analysis is presently in a state of rapid development. A wide variety of technical approaches...
have been applied. Skilled and knowledgeable operators are needed for proper operation of most instruments. Comparison with laboratory analysis remains the standard of PGC performance for the time being. Individual instruments are generally limited to specific classes of compounds, and complete characterization of a complex site may require the use of several types. The use of PGCs to pilot collection of samples for laboratory analysis is becoming accepted, but total reliance upon PGCs for site characterization awaits more extensive and reassuring experience.

Laboratory- and field-based methods of analysis can complement each other. The widely held perception that laboratory-based analyses are more “accurate” because they are done in a stable environment using state of the art equipment is misleading. The futility of accurately analyzing samples flawed by blind collection or lengthy storage is too seldom considered. Likewise, enthusiasts for field-deployable analysis can be tempted to ignore the effects of operating in environments where even laboratory equipment could not perform properly. Ideally, fast laboratory- and field-based methods should be used together.

8.2 Future Prospects
Reliability of data obtained from on-site instruments is not yet generally accepted, but instruments are becoming more sophisticated and user-friendly. As the quality of data continues to improve and consistent performance continues to be demonstrated, on-site data will be increasingly accepted. Eventually on-site data will become the standard by which the integrity of samples analyzed in the laboratory after prolonged storage will be judged. Two principal benefits are expected from faster analyses. The first is quicker access to data. The second is a reduced sample storage time, resulting in better sample integrity and quicker cycling of sample containers. Both laboratory- and field-based analyses have important advantages and disadvantages. Used together, their respective disadvantages cancel, while their advantages reinforce each other.

The analysis of gas and vapors in the field is an important part of the remediation process. The purpose of this article is to familiarize the reader with some of the analytical instruments available today to determine the composition of gaseous samples. Although this section deals with portable instruments, it was found necessary to mention on-site measurements since this is an important part of field measurements. On-site measurements are done with conventional analytical instruments operating from recreational vehicles. The samples have to be collected and the first part of this article gives an overview of some of the techniques, such as canister and solid adsorbents, used for this purpose. Identification of compounds collected on-site or directly in the field can be done by gas chromatography (GC) and mass spectrometry (MS). A comprehensive description of the hardware used with these techniques is provided.

An important part of the portable section covers direct-reading instruments such as gas sensors, electrochemical devices, ionization detectors and colorimetric detectors. These instruments provide only a limited amount of information and, most of the time, require a prior knowledge about the content of the sample. However, they are small, portable and cheaper than laboratory analytical instruments and therefore they have found a market.

Portable instruments include miniaturized gas chromatographs and mass spectrometers. These instruments do not offer the high performance of their laboratory counterparts, but they give more information about the sample than direct-reading instruments. The next step in process measurement sophistication is to combine these techniques. The most popular hyphenated technique is certainly the coupling of a gas chromatograph with a mass spectrometer, but there are also powerful and lesser-known techniques such as GC combined with ion mobility spectrometry (IMS). IMS has found a market with military applications for the detection of chemical warfare agents. It offers less resolution than MS but operates at atmospheric
pressure and is therefore truly portable. When combined with GC it offers some interesting features which will be described.

1 INTRODUCTION

In recent years, the area of environmental laws governing emissions has been one of the fastest-growing areas of legislation. Its primary aim has been to protect the environment by exercising control over emissions from industrial processes. From country to country, different agencies monitor compliance, and failure to meet the standards can result in prosecution and heavy penalties. Sources of emissions can be broadly split into two areas: mobile (vehicles) and stationary (plants). The volume of legislation governing automotive exhaust emissions has been on the increase for some time. Most of this legislation involves the measurement of oxygen, carbon monoxide, carbon dioxide, unburned hydrocarbons, and, to some extent, nitrogen oxides. An instrument used to monitor mobile sources for field measurements has some requirements: it must be small and light, use a minimum of consumable fuel (electrical power and gases), and operate for hours, even days, without need of recharging.

Of primary interest among stationary sources of emissions are the emissions from flues or stacks. The composition of flue gas depends on the fuel or chemical process causing the emission, but the main components are emitted as a result of fossil fuel burning. The gases to be analyzed consist mostly of oxygen, unburned hydrocarbons, oxides of carbon, sulfur, and nitrogen in varying concentrations. The majority of legislation governing emissions is concerned with carbon monoxide, carbon dioxide, sulfur dioxide, nitric oxide, and nitrogen dioxide.

In many instruments designed specifically to monitor a single chemical, interferences are minimized, and concentrations within the healthy range – permissible exposure limit (PEL) and threshold limit value (TLV) – can be reliably and accurately measured. When used correctly and appropriately, measurements made with these dedicated instruments can often be used in lieu of traditional instruments, such as gas chromatographs.

Generally, instruments dedicated to a single chemical are less expensive and easier to use in the field than are instruments that detect many different chemicals, such as GC and broad-spectrum infrared (IR) units. The instruments with broader measurement capabilities can also be dedicated to the measurement of a single chemical, but this is generally not cost-effective. IR instruments dedicated to the measurement of a single chemical are constructed more simply than those with broader monitoring capabilities. One available variation is a single-instrument housing that can be adapted to monitoring different chemicals by replacement of the sensors. The choice of instrument depends on the situation to be monitored; in general, for atmospheres for which the types of contaminants are well characterized, the more specific the monitor the better. On the other hand, with a number of unknowns the more appropriate instrument will be a nonspecific general-survey instrument.

The intent of this article is to provide a guide in choosing non-optical techniques used for the analysis of gaseous samples. The most commonly available technologies are described here, along with descriptions of commercial products using those technologies in practical applications, if available. Most of these techniques are mature, and their theoretical bases well established. On the other hand, the hardware used for field measurements is under continuous development, so information is valid only up to the time of writing. It is important to check the current state-of-the-art information in specialized journals and contact vendors to get updated information about products.

Measurements can be performed off-line by collecting the samples and analyzing them later, generally in the laboratory. Several approaches are described in detail. Sample collection can be discrete (grab sampling, use of canister) or done over time (solid sorbent, impingers). When the decision is made to take a field measurement, the proper analytical technique must be selected. Although many approaches are available, the final decision is based on what is already known about the sample. If the components of the gaseous sample are known and the user wants to determine only the presence and the concentration level of the analytes, the use of cartridge tubes or any other technique based on colorimetry is perfectly acceptable. These tubes are inexpensive, sensitive, and give visual confirmation of the level of the gases present. However, they are irreversible and cannot be used as permanent monitoring devices. Electrochemical sensors are used when an unknown element of the gaseous sample must be determined. These sensors, described below, are relatively selective and sensitive enough to detect gas or combinations of gases at the sub-parts per million level. They can be operated in an alarm (monitoring) condition and are reversible.

Portable monitors, such as the flame ionization detector (FID) and photoionization detector (PID), are also described; they give some useful information regarding the family of compounds of the analytes. They are sensitive and reliable but provide only a little information about the nature of the sample itself. They are easy to use and give the go/no-go information necessary for a quick decision. Several commercial units are described.

The next category of measurements uses instruments that separate the components of the mixture, at least
partially, before detecting them and thus allows quantification of the sample components. Gas chromatographs fall into this category. GC is a mature technology that separates the various constituents of a gaseous mixture before detecting them. GC is not an absolute method of identification.

Since GC identification is based only on the comparison of retention times and not on the physical properties of the analytes, multiple compounds may be eluting at the same time and not be identified. Therefore, it is not possible to detect with 100% certainty all the components of a totally unknown sample. However, GC provides a reasonable amount of information and is so convenient that it is commonly used. It is fast, inexpensive, easy to use, and, when combined with other analytical techniques, such as MS, provides an accurate method of identification. The components of a gas chromatograph, from the injection to the separation to the detection of the sample, are described. Portable units are becoming smaller, more sophisticated, and more versatile. However, the quality of data provided with portable units is still significantly lower than the quality of measurements obtained with laboratory instruments. Some of the portable units available will be described, and the pros and cons of those techniques will be identified.

The next category of measurement is mass dispersion methods. Two of these methods are discussed: MS and IMS. IMS was developed to detect toxic gases in chemical warfare applications. IMS is more qualitative than quantitative. IMS is sensitive (parts per billion level), fast (within seconds), and ideal for detecting suspected gases, but it is not as good at identifying totally unknown mixtures. IMS instruments are portable and easy to use, even by unskilled operators. Since interest in this technique is growing for civil applications, it will be described here. MS, especially combined with GC separation, is the most powerful but also the most expensive and difficult to use analytical tool available. MS provides positive identification, even in complex situations. It is fast (<1 s) and accurate. Its dynamic range is large (in decades) and sensitive. This technique is now becoming portable, thanks to the technological improvements of portable vacuum technics (better material, turbomolecular pumps). It is usually coupled with GC to simplify the interpretation of spectra.

2 TECHNIQUES OF COLLECTION FOR VAPORS AND GASEOUS SAMPLES

2.1 Regulations and Government Agencies

The analysis of air, soil, and water samples is still, and will continue to be, an important component of the overall effort to resolve the environmental problems associated with undesirable and unhealthy chemicals. Environmental laws and regulations and government agencies are obviously major participants in the activities related to the protection of the environment. Any analytical work performed in conjunction with a federal or state regulation or government agency must conform to the guidelines that it provides. A working knowledge of the guidelines and of the capabilities of the various analytical techniques available is essential for any analyst involved in environmental analysis.

At the federal level, the United States Environmental Protection Agency (USEPA) is the most recognized regulatory organization. From the regulatory perspective, the primary function of the USEPA is to interpret laws passed by Congress and to formulate operating practices. Other prominent federal agencies, such as the Department of Energy (DOE), the US Army Corps of Engineers (COE), the Department of the Interior (DOI), the Department of Labor (DOL), the Occupational Safety and Health Administration (OSHA) and the National Institute of Occupational Safety and Health (NIOSH) are also charged with the protection of the environment. Detailed information on a particular government agency or regulation may be obtained directly from the agency.

2.2 Ambient Air Quality Standards

At the federal level, the quality of the air is measured by comparing pollutant concentrations with the National Ambient Air Quality Standards (NAAQS). At the state and local level, it is measured by comparing the pollutants with NAAQS, as well as with state ambient air quality standards (SAAQS) and local ambient air quality standards, if any. Recent legislation (the 1977 and 1990 federal Clean Air Act amendments) has added other parameters, such as esthetics (visibility) and risk (air toxicity), to the evaluation of air quality.

2.3 Atmospheric Dispersion Modeling

Modeling is used to determine what happens to pollutants emitted into the atmosphere. When a pollutant is emitted, it mixes with the existing air, and its concentration decreases because of atmospheric turbulence. This process is termed atmospheric dispersion. Most of the point-source atmospheric models that are used in the regulatory process are termed Gaussian dispersion models. Non-point-source models are used to access regional pollutants (e.g. urban air shed modeling) or vehicle emissions (e.g. freeway or traffic impact modeling). Summaries of preferred air quality models such as SCREEN, SCREEN3, and ISC have been described.
More information can be found in the USEPA guidelines and model handbooks.

### 2.4 Classification of Contaminants

Contaminants may be divided, depending on physical characteristics, into gases, vapors, and particulate matter. The terms gases and vapors are often used interchangeably, although they are not identical. At ordinary temperature and pressure, both gases and vapors will diffuse rapidly. Gases are generally noncondensable at room temperature, whereas vapors are considered to be condensable, since they are derived from volatile liquids. Therefore, under ordinary conditions, gases remain in the gaseous state even when present at high concentrations. Vapors, on the other hand, may condense at high concentrations and coexist in both gas and aerosol forms. Particulate matter can be further differentiated as dust, fumes, smoke and soot, and liquid particles. Dusts are solid particles formed from inorganic or organic materials reduced in size by mechanical processes. These particles range in size from the visible to the submicroscopic, but the principal concern of industrial hygienists is with those under 10 µm in size, because such particles stay suspended in the atmosphere for a long period of time and can reach the deepest parts of the lungs.

Fumes are fine particles formed from solid materials by evaporation, condensation, and gas-phase molecular reactions. These particles range in size from 0.1 to <0.01 µm. Smoke and soot are products of incomplete combustion of organic materials. The size of smoke particles is usually <0.5 µm. Liquid particles are produced by condensation and atomization from the gaseous state. Droplets formed from atomization are usually >5 µm in diameter.

There are two methods for collecting gaseous samples. In grab sampling, an actual sample of air is taken in a flask, bottle, bag, or other suitable container; in continuous or integrated sampling, gases or vapors are removed from the air and concentrated by passage through an absorbing or adsorbing medium. Grab sampling usually involves the collection of instantaneous or short-term samples, normally within a few seconds or minutes. This type of sampling is acceptable when peak concentrations are sought or when concentrations are relatively constant. An important feature of grab samples is that their collection efficiency is normally 100%. However, sample decay does occur for various reasons, such as reaction or adsorption on the inner surfaces of the collector.

Grab sampling is of questionable value when the concentration of the contaminant varies with time or is low, when the measurement device is barely sensitive enough to measure a sample, or when a time-weighted average (TWA) exposure is desired.

Integrated sampling consists of extracting the gas or vapor and concentrating it by solution in an absorbing liquid, reaction with an absorbing solution, or collection on a solid adsorbent. Collection efficiency is frequently <100%; therefore, individual efficiency percentages must be determined for each case.

Guidelines for the selection of sampling devices and analytical procedures are available.\(^4\) Secondary sources are also available in books\(^7\) or in journals such as the American Industrial Hygiene Association Journal and Applied Occupational and Environmental Hygiene.

Generally, nonreactive and nonabsorbing gaseous substances may be collected as grab samples. Gases and vapors that are water-soluble or that react rapidly with absorbing solutions can be collected in simple gas-washing bottles.

Gaseous substances that are volatile and less soluble or that react slowly with absorbing solutions require more liquid contact and may require more elaborate sampling devices. Insoluble and nonreactive gases and vapors are collected by adsorption on activated charcoal, silica gel, or another suitable adsorbent.

### 2.5 Grab Sampling

The preparation steps required for trace analysis of most air or gaseous samples differ from those required for solid or aqueous samples in that they are performed partially in the field; the gaseous samples themselves are never really transported to the laboratory. The organic contaminants contained in these samples are usually extracted or removed from the gaseous matrix and concentrated during the sampling procedure.

In its simplest design, a measured volume of the sample is drawn into the sampling system or directly through the measuring instrument by some type of pump. The simplest sampling system consists of only a collection medium. The analytes are retained on or in the collection medium, which is transported to the laboratory for preparation and analysis.

Gaseous samples can be collected in rigid glass or metal flasks, in soft plastic bags, or in combinations of these with aluminum foil in sizes up to 120 L. For plastic bag sampling, the sample is introduced into the bag by a hand- or battery-operated pump or a squeeze bulb. Pyrex gas-collecting tubes of 300 mL capacity with a capillary standard taper stopcock at each end may be used when the atmosphere sampled contains components incompatible with plastic bag materials. The flask may be evacuated in the laboratory and then opened in the environment to be sampled, or the flask may be evacuated in the field with a pump. Specially passivated stainless-steel pressure canisters are used for short-period sampling of reactive gases and vapors.
2.5.1 Sample Bags

When low detection limits are not required, sample bags are used to collect gaseous samples and are transported to the laboratory for analysis without intermediate preparation steps. Transportation of gaseous samples in this manner is useful only when the analytes of interest are stable and when other methods of collection are not applicable. For instance, bags are used when sorbents have a low breakthrough volume or when collection of TWA samples is required. These bags can be made of plastics but are more often made of materials such as Tedlar, Mylar, Scotchpak, and Teflon®. Figure 1 shows a plastic bag equipped with a septum injector.

The sampling apparatus consists of a 20-L (5-gal) open-top container with a sealable lid, a Teflon® stopcock, Teflon® bulkheads, Teflon® tubing, and a sampling pump. The bag is attached to a low-flow exhaust outlet and to an adjustable pump. The sampling period determines the size of the sample bag and the flow rate of the pump. Most bags have a septum for injection using a syringe.

Personal bags are often used to collect gases and vapors for high-resolution analysis of environmental samples and occupational sampling. This method is commonly used for collecting air samples in open fields and from vapor wells. Bulk air samples are collected in small bags carried by an operator. Personal sampling requires that the collection device be small and light. A pump and a battery are provided with the device and must be carried away by the operator. Sampling bags are used when other methods are not applicable, for instance, when sorbent tubes have a low breakthrough volume or when there is no alternative method. Sampling bags are also used when a mixture of gases is incompatible. Sampling bags come in various materials and shapes but most have a valve to allow for injection filling (with a syringe) using a pump and a septum. Sample losses from bags are caused by leaks, chemical reaction of the sample with the bag walls, adsorption of the sample into the bag material, and permeation of the sample through the walls of the bag.

2.5.2 Evacuated Vessels

In many cases, the sampler simply wants to collect a quick sample of air from a given area. Evacuated flasks and cans can be used for this type of collection. Evacuation-type devices are sealed vessels in which a vacuum has been created, with only one inlet. These devices can be used to collect gross gas contamination. The concentration of contaminants must be high enough to be detected in a small-sample volume.

Evacuated cans, similar to those that hold shaving cream, are available commercially. By pushing in the top of the can, the seal is broken, allowing air to enter. Vacu-Sampler (MDA Scientific, Lincolnshire, IL, USA) is an example of a container completely evacuated in the factory (Figure 2). When the sample is collected, a volume of 120 cm³ of vapor or gas can be obtained. Before use, bulk air sampler bags should be cleaned, tested for leaks, and preconditioned by flushing with the gas to be sampled (if known) or zero air.

2.5.3 Stainless-steel Canisters

Collecting ambient air samples in canisters provides a convenient method of integrating ambient samples over a period of time, such as 24 h. Collection can be unattended and provides enough samples to allow detection of small quantities of pollutants. Two sampling modes are used: passive and pressurized. In passive sampling, an evacuated canister is opened to the atmosphere through a flow restrictor adjusted so that the differential pressure causes the canister to fill over a designated period of time. For pressurized sampling, an initially evacuated canister is filled by the action of a flow-controlled pump from a near-atmospheric vacuum to a positive pressure that should not exceed $1.2 \times 10^{-5} \text{ N m}^{-2}$ (25 psi). Pressurized sampling is used when long-term integrated samples or higher-volume samples are required. Commercial canister units are sold with a filter that traps particulate material. Figure 3 shows a canister used for sampling ambient gas and vapor. Canisters are generally not used for...
the collection of polar compounds, such as methanol, ammonia, and hydrogen chloride, because these adsorb on the walls of the vessel. The list of volatile organic compounds (VOCs) that can be collected is defined in USEPA canister method TO-141.

2.6 Integrated Sampling

Gas and vapor samples may be collected in a solvent with wash bottles, impingers, and absorbers; on adsorbents (e.g., activated charcoal); by condensation; and in large plastic bags that are filled using a battery-operated pump. After sampling, the contents may be analyzed in the field or laboratory by nondispersive IR (carbon monoxide), GC (hydrocarbons, chlorinated solvents), and other methods. Absorber characteristics vary, depending on the gas or vapor to be collected. Simple bubbling devices, such as impingers and Drechsel bottles, are adequate for readily soluble gases such as hydrogen chloride, hydrogen fluoride, and sulfur dioxide. For less easily absorbable materials, such as chloride and nitrogen dioxide, multiple contact washing is required (as with fritted glass absorbers). Sometimes it is desirable to burn the gas or vapors in a furnace and sample the oxidation products, e.g., for chlorinated hydrocarbons.

Adsorption tubes are the method of choice for insoluble or nonreactive vapors. Commonly used adsorbents include activated charcoal, silica gel, and molecular sieves. Gas adsorption traps are sometimes preceded in the device by one or two water vapor adsorption stages containing calcium chloride, calcium sulfate, or silica gel, all of which have excellent water vapor adsorption characteristics and poor adsorption capacity for most organic molecules. In the laboratory, the collected vapors may be desorbed thermally or stripped from the adsorbent with carbon disulfide and the recovered vapors quantified by GC using a suitable detector.

Adsorption tubes used for personal integrated sampling of many organic gases and vapors contain two interconnected chambers in series, filled with gas adsorption charcoal. The first chamber, containing 100 mg of charcoal, is separated from a backup section, containing 50 mg of carbon, by a plastic foam plug. Sampling can be conducted for as long as 8 h without saturating the first chamber when occupational exposures are at or below the TLV. The contents of the two chambers are analyzed separately to determine whether the first-stage adsorbent has become saturated and has lost an excessive amount of the sample to the second stage.

GC column packing materials (e.g., Tenax®) are also used in adsorbent traps for field sampling of organic vapors. They are particularly useful for sampling high-boiling compounds. The resealed trap is returned to the laboratory for analysis. Absorption of inorganic compounds...
atmospheric constituents by liquid coatings on solid supports has been used to collect nitrogen dioxide on triethanolamine-coated molecular sieves.

Chemically active compounds may react with each other or with oxygen in the air after adsorption and make it difficult or impossible to recover and quantify the adsorbed gases and vapors. In such instances, the best collection method may be to react the contaminants chemically to a stable derivative or to condense them at low temperatures using a mixture of dry ice and acetone or liquid nitrogen as the coolant. Direct-reading instruments combine sampling and analytical functions and usually display results rapidly. Many in this category are also capable of storing continuous readings and displaying averages for selected time intervals on command.

Organic compounds and other pollutants present in air can exist either as gases or as particulate matter. These compounds can originate from various manufacturing and mechanical processes as a result of the incomplete combustion of the fuel material or as a result of the spontaneous volatilization of material from a chemical spill, uncontained waste, or uncontained feedstocks. Vegetation sources also release a significant volume of organic compounds into the atmosphere.

Pollutants that exist primarily in the gaseous state are described as VOCs. These are compounds with boiling points typically around or below 100°C and vapor pressures of \( >10^{-1} \text{ Torr} \). The semivolatile organic compounds (SVOCs) have vapor pressures in the range of \( 10^{-10} \text{–}10^{-5} \text{ N m}^{-2} \) \((10^{-10} \text{–}10^{-7} \text{ Torr})\) and can exist in the gaseous phase or in the particle-bound phase, either as an adsorbed material or as a liquid droplet or mist. These adsorbed compounds can remain attached to the particles as they are dispersed through the atmosphere, or they can undergo chemical reaction in the atmosphere. Alcohol, aldehydes, ketones, organic acids, esters, and organic nitrates have been identified as components of organic smog aerosols, which are essentially liquids.

### 2.6.1 Solid Sorbent Sampling

Generally charcoal, silica gel, and Chromosorbs are used for occupational air sampling and Tenax® and carbon molecular sieves are preferred for environmental samples. Since the levels expected are much lower in environmental samples, the collection period is much longer. Typically, environmental samples are collected on a 24-h average. Sampling time and volume must be determined experimentally, based on the overall concentration and the number of components.

Solid sorbents are specific for groups of compounds, and one sorbent will not work with all compounds.8 Most solid sorbents do not differentiate among compounds during collection, so unwanted compounds may be collected along with the target compounds. On the other hand, because of the wide range of vapor pressures and breakthrough volumes for organic gases of interest, there is no one solid sorbent that can collect all gases and vapors simultaneously. Sometimes sorbents are coated with reagents to enhance collection of a specific compound.

The biggest concern in collecting material on a sorbent tube is whether breakthrough can occur. Breakthrough occurs when the front section of a tube is saturated and enough compound accumulates in the backup section for it to begin to exit the tube with the airstream.10

When selecting sorbents, the potential for water absorption must be considered. Both the compound being sampled and the water compete for the absorbent’s surface, resulting in concentrations that appear lower than they actually are. Table 1 lists factors affecting the collection behavior of solid sorbents.11

#### 2.6.1.1 Charcoal Sorbent

Charcoal is one of the most commonly used sorbents, since it is useful for sampling a wide variety of organic gases and vapors, including several different compounds at a time. Ordinary charcoal is activated by steam at 800–900°C, causing it to form a porous structure. Charcoal tubes are generally analyzed using the solvent carbon disulfide to collect adsorbed contaminants. The adsorbing capability of activated charcoal varies from batch to batch. Charcoal tube collection efficiency for various hydrocarbons may be affected by such variables as sampling rate, vapor concentration and totally adsorbed hydrocarbon mass. Nonpolar compounds, preferentially sampled on charcoal, displace polar compounds in charcoal media. Competitive adsorption also occurs among polar compounds. Factors that may contribute to the affinity of the molecules for charcoal

| Table 1 Factors affecting the collection behavior of solid sorbents |
|----------------------|------------------|
| **Factor** | **Effects** |
| Temperature | Reduced adsorption at high temperature; breakthrough volume is reduced |
| Humidity | Water vapor is adsorbed by polar sorbents and reduces breakthrough volumes |
| Flow rate | Varies with type of sorbents; at higher flow, reduces breakthrough volumes |
| Concentration | Breakthrough volumes decrease at highest concentrations |
| Mixture | When several compounds are present, the compound most strongly held will displace the other compounds, down the length of the tube |
| Nature of sorbent | Decreases in sorbent particle size are proportional to increases in sampling efficiency and drops in pressure |
| Size of tube | Breakthrough volumes are proportional to the sorbent volumes |
include hydrogen bonding, molecular size, volatility, and the dipole moment.

Breakthrough volumes are variable and a function of the carbon, temperature, humidity, storage times, and pollutant.\(^{11}\) Since charcoal tubes have been shown to be affected by high humidity, sample volume should be reduced when high humidity is present.

### 2.6.1.2 Silica Gel Sorbent

Silica gel is considered a more selective sorbent than activated charcoal, and gases and vapors are more easily desorbed from it. It is the adsorbent recommended for collecting organic amines, both alkyl and aromatic, such as aniline and o-toluidine.

Factors that affect the dynamic adsorption of materials on silica gel include the size range of the gel particles, tube diameter and length, temperature during sampling, concentration of contaminants being sampled, air humidity, and duration of sampling. Since the polarity of the adsorbed compounds determines the binding strength of silica gel, compounds of higher polarity will displace compounds of lower polarity. Therefore, when attempting to collect relatively nonpolar compounds, the presence of co-existing polar compounds may interfere with collection on silica gel.

Silica gel shows a decrease in breakthrough capacity with increasing humidity. Under high humidity conditions, the sample is lost because of saturation with water vapor.\(^{12}\)

### 2.6.1.3 Molecular Sieves

The carbon molecular sieve is a spherical, macroporous structure, the result of pyrolysis of the synthetic polymeric or petroleum pitch precursors. The diameter of the micropores and their number are responsible for the differences in tube retention volume, adsorption coefficient, and equilibrium sorption capacity for a given compound.\(^{13}\) The limiting factor with molecular sieves is humidity. Carbon molecular sieves are most commonly used to collect environmental samples of highly volatile nonpolar organic compounds.

### 2.6.1.4 Porous Polymeric Sorbents

Porous polymers are another class of sorbent used for air sampling and include Tenax® GC, Porapaks, Chromosorbs 101–108, and XAD tubes. Their wide variety offers a high degree of selectivity for specific applications. Limitations include displacement of less volatile compounds, especially by carbon dioxide, irreversible absorption of some compounds, such as amines and glycols, oxidation, hydrolysis, and polymerization reactions of the sample, chemical changes in the contaminant in the presence of reactive gases and vapors, such as nitrogen oxides, sulfur dioxide and inorganic acids, artifacts arising from reaction and thermal desorption, limited retention capacity, thermal instability, and limitations of sampling volume, flow, and time.\(^{12}\)

The Porapaks are a group of porous polymers that exhibit a wide range of polarity. The least polar member, Porapak P, is used in GC columns, and the most polar, Porapak T, separates water and formaldehyde. Chromosorbs 101–108 are similar to the Porapaks. Chromosorb 101 is the least polar and Chromosorb 104 the most polar. XAD resins include a number of different porous polymer types. XAD-2, the most commonly used, is equivalent to Chromosorb 102 and is used to collect anisidine and tetraethyllead.

### 2.6.1.5 Tenax®

Tenax® is one of the most widely used porous polymers, especially for environmental sampling. It has been used for studies of VOC levels in indoor air. Tenax® is a polymer of 2,6-diphenyl-p-phenylene oxide and can be used to collect organic bases, neutral compounds, and high-boiling compounds. Tenax® is used mostly for sampling low concentrations of volatile compounds.

Tenax® GC has a high thermal stability and can withstand temperatures of up to 350°C, which permits it to be used for thermal desorption. Thermal desorption is desirable because the entire sample is introduced into the analytical system, whereas solvent extraction dilutes the sample and allows only a portion of it to be injected. One limitation of thermal desorption is that the sample can be injected only once. Tenax® has other properties besides its temperature stability that make it useful for concentrating compounds of medium volatility. It is relatively inert and has low, but not zero, affinity for water vapor. Because of its extensive use, its advantages and limitations have been well characterized. It is commonly used for multicomponent qualitative analysis by gas chromatography/mass spectrometry (GC/MS) and quantitative analysis with standards.\(^{14}\)

However, retention or breakthrough volumes for a variety of highly volatile compounds on Tenax® are low.\(^{15}\) Other limitations of Tenax® include a laborious cleanup procedure to control blank problems, a short useful half-life after sample collection, and a tendency to decompose during sampling to produce acetophenone and benzaldehyde; the humidity in the air being sampled may affect sample retention; high concentrations of or a large number of compounds may exceed the retention capacity of the Tenax® bed; and artifact formation may occur owing to chemical reactions during sampling and/or thermal desorption. Tenax® is not effective for low molecular weight hydrocarbons (C\(_4\) and below) and midrange (C\(_5\)–C\(_{12}\)) highly polar compounds.

Tenax® also reacts with strong oxidizing agents, such as chlorine, ozone, nitrogen oxides, and sulfur oxides, to form benzaldehyde, acetophenone, and phenol. Another
documented chemical transformation with Tenax® is that oxidizers react with organics, such as styrene, to produce compounds such as benzaldehyde and chlorostyrene.

2.6.1.6 Other Sorbents Other sorbents occasionally used for integrated gas and vapor sampling include alumina gel and Florisil. Alumina gel, a form of oxide, is rarely used as an air-sampling sorbent except for special applications such as those using formaldehyde. Alumina gel permits a several thousandfold concentration of pollutants. It selectively absorbs polar and higher molecular weight compounds, with the degree of polarity determining the binding strength of a compound on this gel. Alumina gel has been used to collect polar compounds (such as alcohol, glycols, and ketones) and aldehydes, such as formaldehyde. Like all polar sorbents, it has a high affinity for water and thus high-humidity samples are difficult to handle.

Florisil, based on silicic acid, is used for polychlorinated biphenyl (PCB) collection and also for some pesticides. Table 2 lists types and uses of solid sorbents.

2.6.2 Impingers for Solvent Extraction Impingers are suitable for collecting nonreactive gases and vapors that are highly soluble in the absorbing liquid and also those that react rapidly with a reagent in the solution, such as occurs in the neutralization of strong acids and bases. These devices are usually made of glass with an inlet tube connected to a stopper fitted into a graduated vial. The inlet tube rests slightly above the vial bottom. A measured volume of absorber liquid is placed into the vial, and the unit is connected to a pump by flexible tubing. The function of these absorbers is to provide sufficient contact between the sampled air and the liquid surface to provide complete absorption of the gas or vapor. Figure 4(a) and (b) shows how impingers are set up to collect personal samples.

Problems with the use of impingers include condensation of material in the sampling lines and losses by adsorption or volatilization from the equipment.

Figure 4 Personal sampling impingers and bubblers. These devices are usually made of glass and filled with the absorbing liquid. (Courtesy of Gilian Environmental.)
Impingers are bulky and are susceptible to breakage. For these reasons, occupational sampling with impingers is being phased out and replaced by sorbent methods. However, there are still applications, such as in high humidity or when only certain samples (e.g. formaldehyde) are collected, for which the impinger approach is necessary.\(^{(16)}\)

### 2.6.3 Badges

Another passive colorimetric sampling device is the spot plate, or badge. These have indicator strips or buttons designed to change color when a critical accumulation of a given gas is reached. Badges should not be used to warn employees of levels in excess of the PEL. Real-time instruments with audible alarms should be used for these situations. An example of a badge indicator is the ChromAir (Gilian Environmental, West Caldwell, NJ, USA) (Figure 5). This passive monitor badge is for indoor air quality and OSHA compliance screening. The passive monitor relies on the principle of diffusion. The contaminant gas or vapor being monitored diffuses through a series of six cells on the front of the badge, each having an increased resistance to diffusion. After diffusing through the cells, the gas or vapor reacts with an indicator layer containing a specific reagent for the contaminant, and the cells change color. When sampling is completed, the exposure dose is clearly indicated on the opposite side of the badge. ChromAir badges are available for ammonia, acetone, chlorine, carbon monoxide, sulfur dioxide, hydrogen sulfide, nitrogen dioxide, carbon disulfide, methanol, ethanol, hydrazine, and formaldehyde. The sensitivity of these badges depends on the application and is typically in the parts per million range. To obtain the average concentration in parts per million, the exposure dosage (parts per million) is divided by the exposure time in hours.

### 2.6.4 Passive Collection of Gases and Vapors

Passive monitors are lightweight badge assemblies that rely on natural wind currents rather than pumps to move contaminated air to the collection surface. Most of these units are dosimeters that accumulate an average dose and give an integrated measurement. Some units are specific for a given gas, such as chlorine, ammonia, sulfur dioxide, hydrogen sulfide, nitrogen dioxide, carbon monoxide, and mercury. Others can sample multiple gases such as organic vapors. The obvious advantage of passive monitors is their ease and simplicity of use. When used for personal monitoring, they do not interfere with worker activity and are unlikely to affect the behavior pattern of the wearer, whereas wearing a pump with its tubing and media might. The most commonly used passive monitors contain a solid sorbent similar to that used in sorbent tubes. There are also devices that use liquid absorption solutions and passive devices that change color proportional to the concentration present.

Passive devices rely on two basic collection principles: diffusion and permeation. With diffusion-controlled monitors, the mass uptake of the monitor is controlled by the length and diameter of the badge cavity and the physicochemical properties of the contaminants. When permeation is used for sampling, the mass uptake of the monitor is controlled by the physicochemical characteristics of the membrane and the contaminants. The mass uptake is a direct function of the badge permeation sampling rate, the ambient concentration, and the sampling time.

In diffusion devices, the most common passive devices, molecules pass through a barrier or draft shield that minimizes the effect of air currents on a stagnant air layer; they are then collected on an adsorbent material such as charcoal. A concentration gradient is created within the cavity of stagnant air, and the amount of gas or vapor transferred is proportional to the ambient concentration. Each compound has a unique diffusion coefficient for each type of badge. The diffusion coefficient necessary to calculate the final concentration after analysis in the laboratory limits sampled materials to those for which this value is established.

On permeation dosimeters, the gaseous contaminants dissolve in a polymeric membrane and are then transferred to a collection medium, such as a solution. Permeation across the membrane is controlled by the solubility of the gas or vapor in the membrane material and by the rate of its diffusion across the membrane under a concentration gradient. Factors influencing permeation include thickness and uniformity of the membrane, affinity of the membrane for the contaminant, swelling or

---

Figure 5 ChromAir passive monitoring badges from Gilian Environmental.
FIELD-PORTABLE INSTRUMENTATION

shrinkage of the membrane, and possible etching by corrosive chemicals. The efficiency of these devices depends on finding a membrane that is easily permeated by the contaminant of interest and not by the others.

As for diffusion monitors, sampling rates must be determined for each analyte and type of permeation monitor. One difficulty in making such determinations is the need to use thin and fragile membranes to obtain practical sampling rates. The long response times required to reach equilibrium, the sampling rate, and the degree of permeation may be affected by changes in temperature and ambient humidity.

The accuracy and precision of passive monitors depend on sampling time, air currents, and temperature and humidity effects. In the presence of mixtures, passive monitors may be affected by competition among compounds for adsorptive sites, resulting in displacement of one compound by another or preferential adsorption of one compound over another. Passive monitors must be handled with care, since a penetration in the membrane would cause variations in the amount of contaminant collected. Sampling in a dusty environment may also be a problem if the gas being collected is capable of adsorbing onto the dust.

Collection of organic vapors is one of the most common uses for passive monitors. Organic vapor badges contain twice as much charcoal as a typical charcoal tube. The charcoal is usually impregnated in some sort of a matrix. Regardless of the design of the organic vapor monitor, the analytical procedure is generally the same: desorption with carbon disulfide and analysis by GC. The affinity of various compounds for the activated carbon in a badge varies and, because diffusion coefficients exist only for certain gases and vapors, the use of badges is limited to these compounds regardless of the wide applicability of the badges for sampling organic vapors. The accuracy of an organic vapor monitor scan varies, depending on the concentrations being sampled and on the exposure period. The difference in the design of the individual monitors, type of charcoal used, quality control, type of adsorption pad, particle size of the charcoal, amount of charcoal present, surface area of the adsorption material, and membrane or draft shield selection create each monitor’s unique performance with respect to the compounds collected.

3 DIRECT-READING INSTRUMENTS FOR ENVIRONMENTAL MEASUREMENTS

Direct-reading instruments for gases and vapors operate on many different principles. They include detector tubes and instruments such as the FID and PID. Chemical sensors are part of another family of direct-reading sensors that is rapidly displacing some of these techniques. Chemical sensors are currently undergoing intense research and development. These detectors are generally not specific but can be calibrated for a single vapor or known mixture. Gas chromatographs, mass spectrometers, and ion mobility spectrometers represent a distinct class of instruments in that they specifically address the issue of separation as well as detection, and as such they will be discussed in later sections. This section reviews direct-reading instruments. A comprehensive review of direct-reading gas and vapor sensors, electrochemical devices, ionization detectors, optic sensors, and instruments is available.(17)

3.1 Introduction to Direct-reading Instruments

Chemical sensors are a fast-growing part of the direct-reading instrument area. They are found almost everywhere when a single-point measurement such as oxygen, carbon monoxide, or carbon dioxide must be performed. This type of sensor often operates in multisensor combinations. For instance, oxygen meters are often paired with combustible gas detectors. Oxygen measurements are needed not only to evaluate the presence of the concentrations necessary to sustain life but also to evaluate correctly the readings of combustible gas indicators (CGIs). Chemical sensor applications are found almost everywhere: in environmental measurements of air and water, in industrial applications for food and pharmaceuticals, in clinical applications, and in many other applications. This great interest in chemical sensors is due to their small size, low cost, low power requirements, and capability of being integrated into portable instruments. This discussion is limited to gas detection.

Indicator (or detector) tubes are direct-reading industrial hygiene air analysis instruments. They are small, light, hand-operated, and safe in all atmospheres, and generate immediate readouts. In addition, an indicator tube is the simplest and most economical air analysis method available for many common air contaminants. Tube detectors for >160 chemicals are currently available, some in more than one concentration range. The most popular types are offered by commercial sources. Most of the chemicals measured by indicator tubes are included in the current tabulation of American Conference of Governmental Industrial Hygienists (ACGIH) TLVs. Color-developing reagents give point measurements that are almost instantaneous and integrated and that are collected for a long time. The approach chosen is usually dictated by the regulator and by the sensitivity of the measurement device. The instant repartition of specific contaminants may be lost when integrated measurements are chosen over a long period of time, but this
approach is better at identifying contaminants that are harmful to the exposed community.

One of the most important developments in air-sampling technology has been the commercial appearance of passive dosimeters that measure the exposure to low concentrations of a broad list of airborne volatile substances. Many of these dosimeters use the principle of diffusion to a nonspecific adsorbent with subsequent laboratory analysis. These direct-reading devices use permeation through a plastic film barrier to a compound-specific chemical that bonds to color-developing reagents.

Instruments such as the PID and FID respond to a broad class of organic and inorganic gases and vapors and are used widely for survey measurements. The only specificity of these instruments is determined by the class of molecules they detect. For instance, FID meters detect only organic compounds and do not respond to constituents commonly found in air and water. The threshold of specificity of the PID meter is controlled partially by the selectable level of energy emitted by the lamp.

### 3.2 Chemical Gas Sensors

Chemical sensors transform chemical information into electrical signals. These sensors are characterized by small dimensions and relatively low costs and lead naturally to portable instruments for survey and personal measurements. These sensors are generally classified according to the mode of transduction, e.g. electrochemical, optical, or acoustic. Some well-established chemical sensors include electrolyte potentiometric sensors for oxygen, catalytic sensors for combustible gases, and semiconductor oxide sensors. These find use in the detection of both the combustible gases and the toxic gases associated with chemical systems.

New techniques for chemical sensors are emerging, such as field effect transistors, surface acoustic wave (SAW) devices, fiber-optic gas sensors, and pattern recognition methods used with arrays of sensors in so-called electronic noses that evaluate flavors. Solid electrolyte sensors for oxygen and semiconductor gas sensors, based on the response characteristics of a wide range of inorganic oxides and of organometallic materials, are also part of this new generation of sensors. Some of the designs are described below.

Electrochemical sensors with aqueous electrolytes, operating on fuel cell principles, have been adopted widely to meet the growing demand for reliable low-cost gas-measuring devices in safety and process control applications. They are available for the detection of organic and inorganic gases such as ammonia, sulfur dioxide, hydrogen sulfide, chlorine, carbon monoxide, isocyanates, nitrogen compounds, oxygen, phosgene, formaldehyde, ozone, and hydrogen cyanide. General information about chemical sensors and electroanalytical methods is available. Applications of real-time measurements using electrochemical sensors have been published.

The greatest advantage of electrochemical sensors is that they provide a direct relationship between the concentration of gas being measured and the electrical signal at the output (current or voltage, depending on the type of sensor). Also, they can be constructed using well-established engineering methods to produce small, compact devices with a high degree of robustness and reliability, freedom from orientation effects, intrinsically low cost, and suitability for volume production. Such sensors can operate within an ambient temperature range of −20 to 55 °C without the need for external heating. Their power requirements are, therefore, low; some designs are available that are completely self-powered, so that additional power is required only for extrasensor functions such as alarm monitoring, recording, and transmitting data.

A wide range of gas concentrations may be measured using electrochemical gas sensors. Thus commercially available systems to monitor oxygen levels range, e.g. from nearly 100% in medical and gas-purity applications to around 20% for general air quality systems, to just a few percent in flue gas analysis, down to a few parts per million in some gas purity and process control applications. Toxic gases can be measured from around 20% down to a few parts per billion.

Electrochemical sensors do not suffer from variations in ambient humidity, a problem for many semiconductor and solid-state devices. Even through cross-interferences can pose problems, as with any chemical sensor, electrochemical sensors can achieve high specificity when suitably designed and operated.

#### 3.2.1 Principle of Operation of Electrochemical Sensors

The following discussion is limited to potentiometric and amperometric sensors, since they are the most commonly used with portable instruments.

#### 3.2.1.1 Potentiometric Sensors

If a cell signal reflects a change in the potential of the sensor, it is classified as potentiometric. Potentiometric devices have been well studied and can serve as sensors for a variety of gases such as ammonia, hydrogen cyanide, carbon dioxide, hydrogen sulfide, and sulfur dioxide. Potentiometric devices include ion-selective electrodes (of which the pH electrode is a well-known example). These operate on the basis of the Nernst equation, for which electrode potential is a function of concentration (Equation 1):

\[
E = E^* + \frac{RT}{zF} \log C
\]
where $E$ is the potential of the sensing electrode (SE), referred to as the standard hydrogen electrode (SHE), in volts, $E^\circ$ is the standard electrode potential of the SE, in volts, $R$ is the ideal gas constant (8.3143 J K$^{-1}$ mol$^{-1}$), $T$ is the absolute temperature, in kelvin, $C$ is the ratio of the product of the activities of the product species of the electrochemical reaction, written as an oxidation reaction, to the product of the reactant species of that electrochemical reaction (in dilute solutions, activities may be approximated by concentrations), and $z$ is the number of electrons transferred in the electrochemical reaction.

Potentiometric sensors for gases monitor the direct chemical reaction of the gas with the electrolyte, thereby changing the potential of the SE from the initial potential to produce an electrochemical couple with one of the electrolyte ions. The potentiometric sensor observes the potential difference between the SE and another electrode. This difference occurs when the chemical species of choice is detected. The output logarithmically depends on the concentration of the species being detected. The recovery time of the sensor is a function of the concentration of the sample. The higher the concentration, the longer is the recovery time. At a high concentration, the sensor may never recuperate.

### 3.2.1.2 Amperometric Sensors

Amperometric sensors are important in portable instrument design because they are relatively small, inexpensive, and lightweight, and use little power to generate significant signals. These sensors exhibit fast responses, detect parts per million levels of electrochemically active gases and vapors, can be engineered to have significant selectivity, and operate over a wide range of temperatures. Their accuracy is also considered better than that of other methods such as potentiometry. Amperometric sensors are further subdivided into two classes: potentiostatic and coulometric.

In potentiostatic amperometry, an indicating electrode is polarized against a reference electrode (RE) to a constant potential by passing a polarizing current. The sample flows through the cell, and the electric current proportional to the concentration of the species to be measured is recorded. A potentiostatic sensor uses a constant-voltage circuit, i.e. the SE is held at a fixed voltage.

Electrochemical sensors can be categorized as galvanic or electrolytic. A galvanic cell consists of two electrodes and an electrolyte undergoing a spontaneous chemical reaction, which develops an electrical potential difference between the electrodes. The term galvanic refers to any device that can convert chemical energy to electrical energy, be it in a gas sensor, battery, fuel cell, or any other device. Electrolytic is a term applied to the conversion of electrical charges into chemical energy, as in electroplating or charging a battery. Potentiostatic amperometry involves galvanic devices, but requires an external variable current supply to maintain a fixed electrode potential; coulometric amperometry involves electrolytic devices. The process that occurs in these sensors is electrooxidation or electroreduction of the species to be analyzed, resulting in a current. Some require oxygen to function and others do not.

A typical potentiostatic amperometric sensor consists of several major parts: filter, membrane, working (or sensing) electrode, electrolyte, counter electrode, and RE. The gaseous species of interest is transported (by pump or diffusion) across the membrane to the SE of the cell; it then migrates to the electrolyte boundary, dissolves in the electrolyte, diffuses to the electrode surface, and reacts electrochemically. The products of the reaction diffuse away from the electrocatalytic surface.

As a way of understanding this method of detection, a typical potentiostatic curve is shown in Figure 6. Oxidation and reduction current are represented on the $+y$ and $-y$ axes, respectively, while voltage is plotted along the $x$ axis. Below the reaction potential of a given electrooxidizable gas there is no reaction; therefore, the current is zero (except for a small charging effect). As the reaction potential is approached and exceeded, the current rises sharply until it reaches a maximum limited only by the diffusion of the gas to the reaction site. The magnitude of this current is directly proportional to the number of electrons per mole, the Faraday constant, the diffusion coefficient, the surface area of the reaction site, and the concentration of the gas; it is inversely proportional to the diffusion gradient resulting from the varying concentrations of reacting gas that range from the highest concentration found in the electrolyte, to zero concentration at the electrode surface. There is a linear relationship between the current generated and the concentration of the gas. An even further increase in voltage results in

![Figure 6 Basic principles of operation of a potentiostatic sensor. (Courtesy of Interscan Corp.)](image-url)
a high current because of electrooxidation of water to oxygen gas, and no detection takes place.

For the device to work, the sensing (working) electrode must be held at a potential within the region of the limited diffusion current. This is represented by the SE in Figure 6. An RE with a lower or higher oxidation potential than that of the SE is used to maintain the SE in the region of the limited diffusion current. The potential of the RE must not change with the passage of current. Depending on whether the potential of the RE is higher or lower than that of the SE, it will have a voltage that is biased in either the negative or positive direction. The height of the diffusion plateau from the voltage axis is linear with the concentration of the sample present. This is an example of an externally biased sensor. Typical features of potentiostatic sensors include fast response, linear response in a broad concentration range, nonlinear dependence on the flow rate, and temperature dependence of the signal.

Commercial coulometric monitors are constant-current devices. Coulometric monitors measure the quantity of electricity (in coulombs) that passes through a solution during the occurrence of an electrochemical reaction. Therefore, measurement of the amount of electrical energy transferred across an electrode–solution interface (number of electrons) in terms of the coulombs required to carry the reaction of a specific substance to completion is called coulometry. During coulometric sensing, the gas being monitored is consumed by electrolysis during passage through the sensor. The current is controlled by the feed rate of the sample and corresponds to the charge passed in a given time unit (Equation 2):

\[
\text{Current} = \frac{\text{Charge}}{\text{Time}}
\]

(2)

It is generally a wet-chemical titration method in which one of the reactants is generated in the test cell by electrolysis of the solution. These detectors can be made specific by adjusting the concentration, pH, and composition of the electrolyte. An important feature of the coulometric sensor is that the current is, within certain limits, independent of changes in the working electrode; hence the electrode characteristics are unimportant. Electrodes may be constructed from platinum foil, wire, or mesh. The accuracy of the sample flow rate controls the accuracy of measurement and must be kept as constant as possible; the signal is, however, independent of the temperature. Coulometric cells are reusable after being cleaned and recharged with a fresh electrolyte solution.

### 3.2.2 Basic Description of a Fuel Cell Electrochemical Sensor

In its simplest form, a fuel cell electrochemical sensor consists of two similar gas diffusion fuel cell electrodes, a concentrated ionically conducting aqueous electrolyte, a low-impedance external electrical circuit, and a diffusion barrier (Figure 7). In clean air, when reactant gases are absent, both electrodes assume the same potential and no current flows in the external circuit. If an electrochemically oxidizable gas is present, it diffuses to the SE first and causes its potential to shift in the negative direction. The resulting potential difference between the SE and the other electrode, the so-called counter electrode, then causes a current to flow in the external circuit, which is sustained by electrochemical oxidation of the reactant gas at the SE and matched by an equivalent amount of oxygen reduction at the counter electrode.

A carbon monoxide sensor with an acid electrolyte is represented by Equations (3–5):

**Sensing electrode:**

\[
2\text{CO} + 2\text{H}_2\text{O} \rightarrow 2\text{CO}_2 + 4\text{H}^+ + 4e^- 
\]

(3)

**Counter electrode:**

\[
\text{O}_2 + 4\text{H}^+ + 4e^- \rightarrow 2\text{H}_2\text{O}
\]

(4)

**Cell reaction:**

\[
2\text{CO} + \text{O}_2 \rightarrow 2\text{CO}_2
\]

(5)

Carbon monoxide diffuses via the diffusion barrier to the SE, where it is oxidized to carbon dioxide and protons, consuming water and releasing electrons to the external circuit. The carbon dioxide product is rejected by the acidic electrolyte and diffuses out of the cell via the diffusion barrier. Protons produced at the SE migrate to the counter electrode and recombine with electrons and oxygen to form water.

This electrochemical power source is converted to a sensor by the inclusion of the diffusion barrier at the SE of the cell. This barrier is fundamentally important to the operation of the sensor and is designed to restrict access of the reactant gas so severely that it becomes completely oxidized at the SE.
A reactant molecule present in ambient air passes through the following stages in undergoing detection by an electrochemical sensor:

1. mass transport in the gas phase to the diffusion barrier;
2. diffusion, under a concentration gradient, through the sensor barrier;
3. gas-phase diffusion from the barrier to the electrode, through any porous electrode support and into the electrolyte structure itself;
4. diffusion through an aqueous electrolyte film to the catalyst surface;
5. adsorption from the liquid phase onto the catalyst surface, followed by surface migration to the catalyst active sites;
6. electron transfer between catalyst surface and adsorbat, at the active center, to form products;
7. desorption of products and their subsequent transport back into the gas phase and ambient air, and/or into the bulk electrolyte.

3.2.2.1 Diffusion Barrier The nature of the diffusion barrier exerts a profound influence on the characteristics of the sensor. Two broad categories of diffusion barrier have been used, identified according to the diffusion process through the barrier.

In the first type, the rate-controlling process is one of diffusion in solution, sometimes designated activated diffusion. It is characterized by a high exponential temperature effect. The two variants of activated diffusion barriers involve diffusion in solution through an electrolyte film and through a solid polymer membrane.

In the second type, the gas remains in the gas phase as it diffuses through a porous barrier. It is characterized by a relatively low temperature coefficient and also exists in two variants involving either micropores or micropores. The most common barrier employed for macropore diffusion uses a capillary or pore size that is much greater than the mean free path of the gas molecules undergoing diffusion. Here, intermolecular collisions dominate the diffusion process, resulting in a sensor output that has a considerably lower temperature coefficient than do solid-state membranes. It should be mentioned that the sensor will have a $T^{3/2}$ temperature effect.

For barriers in which the pore diameter is much smaller than the mean free path of the reactant gas molecules that occur in the micropore barriers, the molecules pass through the pore, ricocheting off the pore walls with substantially no intermolecular collisions. This diffusion process has fundamentally different properties from the macropore process and leads to different sensor properties. The diffusion rate is determined by the rate of capture of molecules and the molecule velocity. The rate of capture varies as $T^{-1}$ and the velocity as $T^{1/2}$, the combination resulting in proportionality to $T^{-1/2}$. The capture rate, and hence the diffusion rate, vary as $d^{-1}$ (where $d$ is the pore diameter), in contrast to the macropore case, for which diffusion rates are independent of pore size.

Of practical significance is that macropore membrane barriers can be easily fabricated and do not suffer the problems associated with solid membranes. By combining both categories of porous diffusion barriers, the negative and positive temperature coefficients can be offset to produce a sensor with negligible temperature coefficient. (24)

3.2.2.2 Electrodes The electrochemical reactions occur at the electrode–liquid interface, where the solid catalyst surface is in contact with the gaseous reactant dissolved in the liquid electrolyte. To maximize the area of contact, gas diffusion electrodes are employed. (25, 26) These consist of finely divided catalyst powders with large surface areas, mixed with a polytetrafluoroethylene (PTFE) and supported on a highly porous PTFE backing membrane. This design controls catalyst wetting and provides gas channels to the wet electrode interior.

3.2.2.3 Electrolyte The electrodes of an electrochemical sensor are separated by a high ionic conductivity, negligible electronic conductivity medium. All commercial liquid electrolyte fuel cell sensors employ aqueous solutions of strong mineral acids, alkali metal hydroxides, or neutral salts that are absorbed in a separator material between the electrodes, which consists of plastic or glass mats as used in conventional electrochemical power source systems. The electrolyte should have a high boiling point and a low freezing point (typically $< -20 \degree C$).

The choice of electrolyte can affect the electrocatalytic activity of the electrode and can provide a means of controlling selectivity. Some gases are completely inactive, electrochemically, in alkaline media, but react readily in acidic media, while other gases react conversely.

The work in the field of solid ion conductors in the 1950s led to increasing interest in all solid electrolyte cells. A solid-state cell in which the electrolyte was a zirconia-based ceramic was developed in the 1960s for the measurement of oxygen partial pressures. Zirconia sensors have been used in industry ever since, and the technology is now considered mature. A major application for zirconia sensors operating on the electrochemical principle is the monitoring of the air/fuel ratio in fossil fuel combustion systems; this monitoring, combined with closed-loop control, permits maximum efficiency and minimal pollution. Zirconia sensors are versatile and can be tailored to the application; the response time to a change in oxygen gas concentration can be rapid (e.g. 50 ms for oxygen partial pressures $> 100 \text{ Pa}$ at $700 \degree C$).
the sensor can be highly selective to oxygen. Potentiometric devices can measure oxygen pressure levels over an extremely wide range \((10^6 - 10^{-25} \text{ Pa})\); alternatively, amperometric devices deliver a linear response, which is preferred in some applications. It is likely that zirconia sensors will continue to dominate the oxygen-sensing market for applications requiring operations at moderate and elevated temperatures\(^{(27)}\).

### 3.2.2.4 Two-electrode and Three-electrode Designs

In its simplest form, a fuel cell sensor comprises two electrodes connected by a load resistor. Such a device is self-powered, and the voltage developed across the load resistor \(R_{\text{load}}\) by the system constitutes the signal from the sensor. The response time of the cell increases proportionally with the current. The lowest possible value is desirable, and an alternative approach consists of using a potentiostatic circuit that runs the cell at nearly zero current. The equivalent circuit is shown in Figure 8(a).

A larger problem with the two-electrode approach derives from polarization at the counter electrode, particularly when an oxygen reduction counter electrode is used. Such a counter electrode has the advantage of unlimited capacity for ambient air monitoring but has the disadvantage of significant polarization. The SE potential must follow the counter electrode potential fairly closely. Changes in potential of the SE can cause interfering currents from side reactions caused by other electrochemical couples.

A practical consequence is that the useful concentration range of such two-electrode sensors is limited. However, they are simple and self-powered and, therefore, are used successfully commercially.

The effect of polarization at the counter electrode can be completely eliminated electronically using three-electrode sensors (Figure 8b).

In a three-electrode sensor, all three electrodes may be constructed of the same material. The way in which they are connected to the circuit determines whether they are sensing, counter, or reference electrodes. The SE interacts with the gas to be monitored. The counter electrode acts as an electron sink for anodic sensing reactions by completing the circuit for the sensor. The third electrode acts as an RE. No appreciable current passes through the RE, because it is connected to the high impedance input of an amplifier. The RE provides a bias reference for either an applied or an internal potential, so that the SE is at a potential within the region of the limited-diffusion current. Using a potentiometric feedback between the RE and the SE maintains the latter at a constant potential.

As with a two-electrode circuit, the signal is determined by the voltage generated across \(R_{\text{load}}\), except that an amplifier with negative feedback is used to maintain a constant potential relative to the RE at the ground side of the load resistor. This potential is independent of the counter electrode potential. With this arrangement, the change in potential of the SE is due solely to the current generated at the SE by the reactant gas; this current is used as the signal.

Three-electrode circuits also allow the SE potential to be biased with respect to its rest potential, which can be beneficial in promoting desired reactions that do not occur at the RE potential.

### 3.2.2.5 Construction of a Typical Gas Electrochemical Sensor

There are two basic types of sensor designs available commercially, depending on the electrolyte (alkaline or acidic) and the operating principle (metal–air battery or fuel cell).

The construction of an alkaline metal–air, capillary-type oxygen sensor is shown in Figure 9. Conventional nickel–cadmium battery hardware is used for the containment can, which is filled with a lead anode material. This containment can also act as the counter electrode electrical output. A sealing grommet holds the oxygen-reducing SE assembly, which inserts into the top of the anode can after electrolyte charging. Cell closure and sealing are effected by crimping the anode can over the grommet, thus avoiding electrical contact with the cathode\(^{(28)}\).

Various modifications of sensors are possible. For example, one manufacturer may choose to acidify slightly the hydrogen peroxide electrolyte in a sulfur dioxide conductimetric sensor to decrease the effect of certain
interferents. The gas exposure path can be modified to obtain differing gas flow rates that reach the electrode, thus affecting the magnitude of the signal. In units with active sampling, high flow rates are used to pull gases to the sampling electrode to obtain the highest sensitivity. Control of the electrode exposure area is important, and in practical designs as much catalyst as possible is packed into this area (by using material with high surface area) to ensure adequate reacting capability and high sensitivity. Each chemical species has its own unique interaction at an electrode, but for almost all the electrochemical cells, the primary variables are working electrode potential, analyte concentration, current, and time.

The construction materials of the sensor also influence its operating characteristics. Choosing construction materials and sensor geometry is critical and has a profound influence on the accuracy, precision, response time, sensitivity, background signal, noise, stability, lifetime, and selectivity of the resulting sensor. For example, selection of a gold rather than a platinum electrocatalyst for the SE allows for the selective determination of hydrogen sulfide in the presence of carbon monoxide.

Membranes are usually chosen for their ability to protect the SE. However, if the membrane has a low permeability to air, the sensor will have a slow response time. Materials used for the membrane construction are typically Teflon® and high-density plastics such as polypropylene, because such materials must be compatible with reactive gases and corrosive electrolytes.

It is important to select the proper electrolyte for each sensor, since the electrolyte composition can affect the solubility and the rate of diffusion of the reactant gas to the electrode (catalyst) surface. Electrolyte composition can also alter the chemical being monitored before it reaches the electrode surface. For example, the use of an acidic electrolyte to detect ammonia causes the formation of an ammonium ion that may not be as electrochemically active as ammonia under the conditions of the cell. The electrolyte profoundly influences the response characteristics observed for sensors with strongly acidic and basic electrolytes.

Another means of chemically controlling the sensor properties is by altering the composition of the electrocatalyst. Each catalyst formulation has unique properties. The reactivity of platinum with carbon monoxide oxidation has been found to be $10^3 - 10^6$ times better than that of gold. Although both reactions occur on metal, one is orders of magnitude faster than the other.

The selectivity of the sensor can also be improved by controlling the electrochemical potential of the working electrode. For instance, proper selection of a gold electrode potential allows the determination of nitrogen dioxide in the presence of nitric oxide. Response time, linearity, zero drift, repeatability, sensor stability, and even sensor life depend on sensor design and methodology.

As noted, gas sensors are often covered with a membrane that is selectively permeable to a given contaminant. This membrane minimizes the likelihood of poisoning the electrodes by an electroactive and surface-active species. The resolution of these systems is also enhanced if other contaminants (interferents) that also undergo electron transfer at the electrode can be excluded by tuning the circuitry. The appropriate choice of electrocatalyst can help in achieving selectivity in some applications. However, although choosing a membrane or an electrolyte for its selectivity is a good idea, it does not eliminate all the possible interferents, since virtually any compound for which a similar type of detection method is used is a potential interferent.

3.2.3 Multiple Gas Instruments Based on Gas Electrochemical Sensors

Multiple gas instruments that are able to monitor several gases at the same time are available. Advantages to this approach are almost simultaneous monitoring of various gases at a low concentration level without need for a separation column, the low cost associated with the use of electrochemical sensors, relatively fast access to the information, and portability caused by the small
dimensions of the sensors. The principal goals of such a system are to control the sampling conditions and to limit cross-sensitivities to other compounds.\(^{(29)}\)

Figure 10 shows a typical arrangement for a multisensor system equipped with a water trap, particle filter, pump, and in-line SO\(_x\)–NO\(_x\) filter. Moisture condensing from the gas stream can cause blockages and flooding, and absorbs sulfur dioxide and nitrogen dioxide from the sample. Any water, therefore, must be removed as soon as it condenses. The gas stream must also be cooled to the ambient temperature. The particle filter should trap solid particles but not remove any gas the user wants to measure. The choice of the materials in contact with sampled gas should have low absorption properties.

Figure 11 shows the Minigas Multigas monitor from Neotronics of North America, Inc. The Minigas is a confined space gas detector that can display up to four gases:

- oxygen (0 up to 35%);
- flammable [percent lower explosive level (LEL) 0–99%];
- up to two toxic gases: carbon monoxide, hydrogen sulfide, sulfur dioxide, or chlorine.

The sensitivity of the Minigas for toxic gases varies with the nature of the gas. The unit can detect 0.1 ppm of chlorine and 1 ppm of the other gases. The sampling is either by diffusion or with an optional internal pump.

The Minigas can operate on nonrechargeable batteries (40 h minimum with four AA batteries) or with a rechargeable battery (nicad, 12–15 h; NiMH, 21 h minimum). The dimensions of this instrument are depth 1.75 in (4.6 cm) × width 2.75 in (7.0 cm) × length 7.12 in (18.5 cm). It weighs less than 31 oz (831 g) with the zinc rechargeable battery version. The Minigas is equipped with an alphanumeric liquid display which simultaneously gives the reading of gas concentrations and is programmed to give an audible alarm.

### 3.2.4 Typical Performance of Gas Electrochemical Sensors

Typical performance data for electrochemical sensors are given in Table 3. Signaling the presence of a hazardous atmosphere is often more important than measuring its precise content, at least for portable monitoring instruments. Safety sensors do not normally need to have a range capability far in excess of the legal exposure limits. It is apparent from Table 3 that these sensors are small and portable.

#### 3.2.4.1 Typical Linearity Curves

For low concentrations, i.e. below a few percent of reactant gas, the sensor outputs are linear with respect to reactant concentration (Figure 12a). Figure 12(b) shows the error that results from assuming a linear response over the concentration range on calibrating in air at 20.9%. At concentrations above a few percent, sensors become increasingly nonlinear and require some partial electronic compensation.

3.2.4.2 Design Parameters Affecting the Selectivity of an Electrochemical Sensor  Two key features of sensors are that they be highly specific and exhibit minimal effects from cross-interfering gases. Three possible approaches to reaching these goals are to develop specific electrode catalyst and electrolyte systems, control the operating potential of the SE, and use chemical filters to remove interfering gases selectively. Each method has limitations in practice. For instance, electrocatalysts can be developed that exclude some potential cross-interfering compounds, but it is difficult to develop specific catalysts that are sufficiently reactive toward the less reactive gases and do not respond to the more reactive cross-interfering substances.

The selectivity of the sensor can also be improved by controlling the electrochemical potential of the working electrode. For instance, proper selection of a gold electrode potential allows the determination of nitrogen dioxide in the presence of nitric oxide. Response time, linearity, zero drift, repeatability, sensor stability, and even sensor life depend on sensor design and methodology.

Chemical filters placed in the main gas stream of the input sensor remove cross-interfering gases by selective adsorption, chemical oxidation, or reduction. These reactions can be specific. The main disadvantage of this technique is its short filter life; as the filter is exposed to the full gas stream and reaches exhaustion, it must be replaced or regenerated periodically. An alternative and much more efficient method is to place the filter between the electrode and the diffusion barrier.\(^{28}\) In this design, the filter material is exposed to the relatively much smaller amount of interferent gas diffusing to the electrode.

Most applications involve ambient air monitoring, for which the background gas is essentially nitrogen plus oxygen and remains constant. However, if the composition changes, recalibration of the sensor to the new environment becomes necessary. This is called the background effect.

3.2.4.3 Limitations of Electrochemical Sensors  Operating temperature of these sensors is typically from −20 to 50 °C. This is not a problem for most applications, but the user should be aware that lower temperatures tend to result in longer response times. When the sensors are used outdoors in cold climates, ambient temperatures should be monitored to ensure that they do not fall below the lower limits.
Electrochemical sensors designed to measure specific toxic gases may have cross-sensitivities to other compounds. Response specificity is determined by the semipermeable membrane selected, the electrode material, and the retarding potential (the potential used to retard the reaction of gases other than those being sampled). The primary gases that interfere are those that other electrochemical sensors are designed to monitor, because they are easily electrooxidizable or electroreducible. Gases that cannot be oxidized or reduced, such as methane, do not interfere.

Interference can be eliminated with selective chemical filters or by prescrubbing the sampled atmosphere. Both of these methods have been used by manufacturers for some applications. However, not all interfering gases can be eliminated, and the sampling professional must be familiar with those that may pose a problem.

Poor stability of a potentiostatic sensor is primarily due to the effect of temperature on the inherent background current present in every sensor. This current is due to internal electrooxidation or electroreduction. Most passive electrochemical sensors should not be exposed to the air when not in use, as the water loss from evaporation through the porous membrane will shorten the sensor life.

Sensor longevity is also a function of the gases being tested. Since most chemical sensors depend on a specific chemical reaction to generate a signal, the reactions involved in these sensing mechanisms are often not sufficiently reversible, so that the sensitive material (electrolyte) is used up during the life of the sensor. Sensor lifetime has many determinants, including heat, humidity, dirt, and cumulative gas exposure; the importance of maintenance should not be underestimated. Sensors need periodic recalibration; costs associated with calibration represent the majority of expenses associated with these sensors.

3.2.5 Thermochemical Sensors

Gases and vapors have certain thermal properties that can be exploited during analysis. For the instruments used in industrial hygiene applications, one of two thermal properties, conductivity or heat of combustion, is measured.

The thermal conductivity detector (TCD) is a simple device that operates on the principle that a hot body loses heat at a rate that depends on the composition of the surrounding gas, i.e. the ability of the surrounding gas to conduct heat away from the hot body can be used as a measure of the composition of the gas. In usual practice, a TCD consists of an electrically heated element or sensing device whose temperature at constant electrical power depends on the thermal conductivity of the surrounding gas. The resistance of the sensing device is used as a measure of its temperature. TCDs are universal detectors, responding to all compounds that have a different thermal conductivity than the ambient air. They have large dynamic ranges, of the order of $10^3$, and limits of detection of the order of 10–100 ppm for most analytes. TCDs require good temperature and flow control.

The heat-of-combustion detectors, which make up the largest single class of direct-reading instruments for analyzing airborne gases and vapors, measure the heat released during combustion or reaction of the contaminant gas of interest. The released heat is a particular characteristic of combustible gases and may be used for quantitative detection. The heat mechanism in combustion instruments employs catalysts – catalytically heated filaments or oxidation catalysts. This mechanism may measure either resistance change or temperature change via thermocouples or thermistors.

The sensor contains pairs of elements, each containing a platinum wire coil embedded within a catalytic bead bed. An active detector element oxidizes combustible gases, while an inert reference element compensates for changes in ambient conditions. Both elements are in a Wheatstone bridge circuit and the out-of-balance signal produced is proportional to the concentration of combustible gases.

Each heat-of-combustion detector is specific to some combustible gases. Some specificity can be introduced by manipulating the temperature to combat interfering gases or by carefully selecting the oxidation catalyst. Combustible gas instruments also use a semiconductor as the sensitive element. Semiconducting properties can be altered by adding doping impurities. These oxide coatings can be designed to accelerate selectively the oxidation of certain compounds, thus providing more specificity than does a conventional catalytic combustion sensor. Many instruments can detect both combustible gases and toxic gases. When specificities are needed, sensors with the appropriate selective characteristics are installed. The combustible gas sensor has a broad response to various combustible gases and is left unmodified. Selectivity is made possible through different mixtures of oxides and selected operating temperatures.

3.2.5.1 Limitations of Thermochemical Sensors

Thermochemical sensors for combustible gas measurements are used primarily for occupational measurements near sources of combustible material. The CGI was the first direct-reading instrument to be developed. Their initial use was to detect explosive methane in mines. A variety of CGI designs are on the market, ranging from simple sensors to sophisticated microprocessor-based units with multiple detectors. Prolonged exposure to certain substances (e.g. silicones, chlorinated hydrocarbons, and lead- or sulfur-containing compounds) results in an
irreversible decrease in the sensitivity of thermochemical sensors. Some compounds (e.g. halogenated hydrocarbons) can temporarily inhibit performance, but sensors normally recover after a period of operation in clean air.

3.2.6 Other Types of Chemical Sensors

3.2.6.1 Semiconductor-type Gas Sensors Among other types of chemical sensors, the first type of sensor based on adsorption of gases on metal oxide semiconductors was developed by Figaro Engineering over 30 years ago. The gas to be detected is adsorbed on the surface or reacts with the reactive surface oxygen (adsorbed oxygen) of the oxide semiconductor. This induces a change in its surface space-charge layer, which is then converted into a change in electrical resistance of the polycrystalline elements. The gas recognition is carried out through the surface chemical processes; more specifically, the adsorption or reaction sites play the role of receptor for the gases. On the other hand, the conversion of such an interaction to an electrical resistance change is carried out through the physical processes that cause the transport of electrons. This is determined not only by the semiconducting properties of the oxide used but also by the microstructure of the element, such as the grain size of semiconductor particles, and the geometry of the connection between particles.

The metal-oxide semiconductor (MOS) is another category of gas sensor. It is a device in which the conduction between the source and drain is modified by a charge or potential on the gate electrode. Because they are able to detect changes in charge or potential, MOS transistors have been investigated as possible chemical sensors. For example, if ions are absorbed or adsorbed onto the gate, the charge on the gate is modified, which leads to a detectable signal. This can occur by a number of different mechanisms. Either the gas can interact chemically with the gate material and change the carrier concentration on the gate, and hence its Fermi energy, or the gas can induce dipoles in the gate that alter the potential gradients at the gate–oxide interface, or a change in a chemical cell can occur between the gate and the oxide.

Semiconductor gas sensors are based on devices that are manufactured using silicon technologies. Various types of sensors have been developed using either this or MOS transistor technology, in which the material used to fabricate the base is palladium instead of polysilicon and thus has a high selectivity for hydrogen. Sensor technology is based on the ion-sensitive field effect transistor (ISFET), for which an ion-sensitive membrane provides selectivity.

These types of solid-state sensors detect a variety of gases: hydrogen, ammonia, unsaturated hydrocarbons, saturated hydrocarbons, carbon monoxide, hydrogen sulfide, alcohol, arsine, and oxygen. Many reviews of these technologies are available.

3.2.6.2 Surface Acoustic Wave Sensors for Gas Sensing Devices that exploit the transmission of SAWs have been used in electronic applications for more than two decades. The principle of operation of an SAW for gases is conceptually simple. An SAW – a periodic deformation of the normal surface – is transmitted across the surface of a solid, which is presented to the atmosphere to be analyzed. If the solid is a piezoelectric crystal (PZX), then the wave can be induced electrically. The transmission of the SAW is sensitive to the mass of material adsorbed on the surface and may be damped by the environment. It is altered by the interaction of gaseous analyte molecules with the surface, usually via an intermediate (coating) layer; the process is monitored by measuring changes in the frequency, amplitude, or phase of the transmitted wave.

There are many reports of SAWs being proposed as gas detectors, and these reports identify the problems associated with the choice of coating, the specificity, the coating thickness, and the obtaining of reproducible amounts of polymer coating on the surface of the sensing element. Applications of SAW devices for the detection of nitrogen dioxide, hydrogen, sulfur dioxide, and hydrogen sulfide have been investigated. Sensitivity is sample dependent and is typically at the level of a few parts per million. Strong effects on the performance of the detectors at ambient temperature have been reported.

SAWs have been used to sense a variety of organic gaseous species such as nitromethane, methanol, propanol, benzene, tetrachloromethane, N,N-dimethylacetamide, 1-butanol, 2-butanol, diethyl sulfide, 1,2-dichloroethane, isooctane, methanesulfonyl fluoride, and tributyl phosphate.

3.2.6.3 Optical Fiber Gas Sensing The development of inexpensive, high-quality optical fibers for the communications industry has provided the essential component for the development of optical fiber sensors. The physical principle underlying optical fibers is that of total internal reflection. If a material with a higher refractive index (the core) is surrounded by a material with a lower refractive index (the cladding), then repeated total internal reflections result in optical energy traveling along the core. This structure can be planar for waveguides or cylindrical for optical fibers. The evanescent wave is important for sensing applications, because it can interact with analytes outside the light-guiding core by absorption, luminescence, or scattering, thereby modifying the characteristics of the guided light.
There are several advantages for sensor applications, such as small size and flexibility (typically a 200-µm plastic-clad silica fiber can be bent around a 1-cm radius mandrel). The current development of polyimide, amorphous carbon, and metallic coatings means that fibers can operate at temperatures of up to 400°C. These fibers operate remotely up to several kilometers without significant degradation of performance. In addition, fibers can be multiplexed, meaning that expensive optical equipment can be shared. They are intrinsically safer when flammable or explosive reagents are present.

Most of the disadvantages of optical fiber gas sensors are associated with the multiphase chemical-sensing technique. For instance, the response time of the sensor, which is determined by the mass transport in the reagent phase, is directly related to the thickness of the immobilized reagents; response times of the order of minutes are not unusual. Another common problem is that the sensitivity of the sensor can change when the chemical properties of the immobilized reagents change.

Optical fiber sensors can be subdivided into two types: extrinsic and intrinsic. For extrinsic sensors, the optical fiber merely acts as a light-guiding link between the measurement point and a remote spectrometer. With this approach, the optical properties of the analyte are modified by an added reagent and measured directly. For intrinsic sensors, the fiber, probably in some modified form, is the sensing element. The refractive index or the effect of temperature on the optical transmission can be used for this type of measurement. The examples that follow are illustrative of the capabilities of optical fiber sensing.

Methane has been detected at a level of 700 ppm by an extrinsic sensor and a remote spectrometer at a distance of 1 km from the source. Measurements over even longer distances (up to 5 km) have been demonstrated, showing a decrease in sensitivity but still giving useful data.\(^{(49)}\)

Irreversible sensors using immobilized reagents have detected hydrogen cyanide in air within 1 min at parts per million levels.\(^{(50)}\) The irreversibility limits its potential applications.

One example of a sensor that is based on luminescence quenching is that for oxygen under partial pressure in the range 0–20% oxygen with an accuracy of 0.4%.\(^{(51)}\) Another gas that has been detected by fluorescence quenching is sulfur dioxide in the range 0.01–6%.\(^{(52)}\) Nitrogen dioxide, hydrogen chloride, and chlorine have been detected in the 1–10 ppm range using luminescence quenching of a tetraphenylporphine Langmuir–Blodgett film.\(^{(53)}\) One important limitation is again the irreversibility of the sensor.

For intrinsic sensors, interaction with the analyte or an immobilized analyte-sensitive reagent can occur only within the waveguide or in its vicinity (by an evanescent wave interaction). Sensors based on the principle of direct propagation of light through the reagent phase have been shown to be reversible up to around 10 ppm for ammonia gas and 5 ppm for hydrogen chloride gas.\(^{(54)}\)

Evanescent wave sensors using planar and cylindrical optical waveguides have been described. Ammonia concentrations as low as 60 ppm were detectable within 1 min.\(^{(55)}\) In this application, a coated capillary tube was used instead of a solid glass rod to increase the number of reflections with the outer surface and hence the sensitivity. Methane has also been detected without the addition of any further reagent at a concentration level of 5% in air.\(^{(56)}\) Another interesting evanescent wave sensor is an integrated optical device designed to sense hydrogen at a level of 20 ppm but with a response time of several minutes.\(^{(57)}\)

### 3.2.6.4 Surface Plasmon Resonance Sensor

Surface plasmon resonance can also provide the basic transduction mechanism for optical gas sensors. A surface plasmon is a particular form of electromagnetic wave that propagates along the surface of a metal. It can be excited optically by light undergoing total internal reflection at the surface of a glass substrate onto which the metal film has been deposited (Figure 13a and b). With the proper choice of metal, usually silver or gold with a thickness of a few nanometers, excitation occurs at a particular angle of incidence, leading to a sharp dip in the intensity of the reflected beam at that particular angle. This angle depends on the surface plasmon's resonant frequency and is sensitive to variations in the refractive index of the medium immediately adjacent to the metal surface. The sensitivity of the resonant frequency to variations in the refractive index of the neighboring medium falls

![Figure 13](image)
exponentially as a function of distance from the metal surface, having the same form as and a similar decay constant to the evanescent field interaction discussed previously. This principle of analysis has been applied to anesthetic gas concentrations with a detectable limit of 10 ppm and a response time of 1 s.\(^{(58)}\)

3.3 Detector Tubes and Other Colorimetric Direct-reading Indicators

Detector tubes and other direct-reading colorimetric indicators are sampling media that change color when exposed to contaminated gases or vapors. A typical sampler is a glass tube filled with a solid granular material that has been coated with a chemical substance that reacts to change when contaminated air moves through the tube. The primary use of these devices is for occupational sampling, since they are generally not sensitive enough to detect the low levels of contaminants measured in environmental detection.

Three types of colorimetric indicators are used for determining contaminant concentration in air: liquid reagents, chemically treated papers, and glass detector tubes that contain solid indicating chemicals.\(^{(59)}\)

Liquids reagents determine alkaline gases by measuring the volume of air required to produce a color change. This method is somewhat inconvenient and requires skill but is capable of good accuracy. Convenient laboratory procedures using liquid reagents have been simplified and packaged for field use. Reagents are supplied in sealed ampoules or tubes and are diluted at the time of use. Unstable mixtures are freshly prepared by mixing the ingredients at the time of the measurement.

The TDI/MDI Analyzer Kit (Sensidyne, Inc., Clearwater, FL, USA) is based on liquid reagent technology. It provides a rapid method for field determination of toluene diisocyanate (TDI) and methylene bis(4-phenylisocyanate) in air. A sample is drawn through a special absorbing solution using the BDX 55 pump and a midget impinger at 2.8 L min\(^{-1}\) (0.1 ft\(^3\) min\(^{-1}\)) for 10 min. The solution is transferred to a test tube, and a series of reagents are added to produce a blue–red color. The color is compared to a color reference card graduated in parts per million by volume. Results within 0.01–0.35 ppm limits can be obtained in about 30 min. This approach is labor intensive and not geared for fast analysis but should be mentioned since it is the basis of all colorimetric measurements.

Chemically treated papers are used to detect and determine the nature of toxic gases. The method is simple, convenient, and compact. Papers may be used wet, dry, or freshly prepared, as needed. Special chemical chalks or crayons are also used to sensitize ordinary papers to gases. Semiquantitative determinations may be made by hanging the paper in contaminated air. The accuracy of such a procedure is limited by the fact that the volume of air sample is rather indefinite and the degree of color change in the paper is influenced by air currents and temperature. More accurate quantitative results may be obtained by using a sampling device capable of passing a measured volume of air. Visual evaluation of the stains on the paper may be made by comparison with color charts or by photoelectric instruments.

Tape-based instruments make up the next level of sophistication of chemically treated papers that can provide quantitative results. These instruments can be purchased as dedicated systems or as instruments in which different cassettes can be inserted depending on the nature of the gases to be monitored. In either case, the instrument will sample only one chemical at a time and has poor selectivity. An example of a toxic gas monitor using a gas detector cassette tape is shown in Figure 14.

During exposure to a contaminant, the reaction produces a continuous characteristic stain on the paper tape. After exposure, the tape is moved incrementally to an optical reader. The reflected optical density of the stain, which is proportional to the concentration of the contaminant in the air, is compared with the reference reflectance and displayed on a meter. The advantage of the optical reader is that the system is calibrated optically and does not require gases for the calibration of the instrument. The disadvantages of this approach are the intermittent nature of this type of detection and measurement as used with paper tapes and the relatively long response time of the system (typically 60 s).

The model FP-250A from RKI Instruments, Inc. (Hayward, CA, USA) uses cassette tapes impregnated

**Figure 14** Gas monitor that uses a gas detection cassette. (Model FP-250A from RKI Instruments, Inc.)
with various reagents to obtain a selective detection. Gases such as hydrogen sulfide, phosphine, and arsine can be identified, but potential interferences will not be detected if both gases are present at the same time. Consequently, this type of instrument is best adapted to monitor the level of toxic gases of a known nature such as phosphine. The minimum detection level also depends on the gas monitored. Arsine, for instance, is detected at the 2.5 ppb level in 20 s, whereas it takes 60 s to detect silane at a 250 ppb level with the same tape.

Detector tubes are available for short-term measurements (grab sample measurements) or long-term measurements (dosimeters). Short-term measurements take typically 1–2 min, whereas long-term collection can take 4–8 h, using either active or passive methods. Active methods involve the use of a portable battery-powered pump or hand-powered pump. Passive methods, such as the badges described earlier, rely on diffusion.

3.3.1 Applications of Detector Tubes

There has been a great expansion in the development and use of detector tubes, and more than 400 different types are now available. Detector tubes are convenient for quantitative and qualitative evaluations of toxic hazards in industrial atmospheres and process control and for the rapid evaluation of spills of hazardous materials. Detector tubes are also used for detecting explosive hazards, checking compressed breathing air, and confirming carbon monoxide in exhaled breath or in gas released from a sample of blood. They are used for law enforcement to measure alcohol in the breath and signs of arson. Several manuals provide comprehensive descriptions and listings.

Detector tubes are simple, fast, inexpensive and easy to use, but are also subject to many limitations and potential errors. The results may be dangerously misleading, so the sampling procedure should always be supervised and the results interpreted by an adequately trained operator.

3.3.2 Operating Procedure for Detector Tubes

The use of detector tubes is extremely simple. After its two sealed ends have been broken open, the glass tube is exposed to a known quantity of air, using either a calibrated squeeze bellows or a piston pump. The observer then reads the concentration in the air by examining the exposed tube. More recently developed types of tubes interpret the length of the stain produced on the indicator gel rather than color changes. The stain length is measured against a calibration scale that can be printed either directly on the tube or on the provided chart. Selection of the detector tubes depends on the chemical for which monitoring will be done and on the concentration range of interest.

3.3.3 Specificity and Sensitivity of Detector Tubes

Many tubes exhibit cross-sensitivity to other gases, and the manufacturers’ literature should be consulted before use. Most tubes are not specific. In the presence of mixtures, the tube reading should be interpreted by a trained operator. The lack of specificity of some tubes may be an advantage for detection of substances not indicated by the manufacturer, but such use requires specific knowledge of the identity of the reagent and of the proper correction to the calibration scales. Most of the tubes are generally designed for detection of relatively high gas concentrations (a few parts per million).

3.3.4 Equipment

Figure 15 shows two models of pump sold by National Dräger. The Accuro bellows pump and short-term detector tubes form a portable sampling unit for use in measuring concentrations of various gases and vapors. Dräger detector tubes are available for measuring approximately 350 air contaminants and for gas analysis. The pump delivers 100 mL of sample air with each pump stroke. After a prescribed number of pump strokes, the stain length or the discoloration of the tubes gives a direct measure of the gas or vapor concentration. Calibration scales are printed directly on most types of tubes. The Accuro is a modular system. For large-volume measurements, the Accuro slides into the electronically programmable Accuro 2000. The Quantimeter 1000 is a programmable, battery-operated bellows pump with the same flow characteristics as the hand-operated pump and is intrinsically safe. The complete Dräger Accuro Deluxe Pump Kit with spare parts and tube opener weighs approximately 1.5 kg.

Figure 15 Dräger Accuro, Accuro 2000, and Quantimeter 1000. The figure shows the tubes operating in a manually and electronically programmable pump. (Courtesy of National Dräger, Inc.)
(3.3 lb). The detector tubes are usually specific for particular gases and vapors. This specificity is achieved not only by the use of specific and stable reagents but also by the use of precleansing layers placed in front of the actual reactive layer to absorb selectively interfering components that may be contained in the gas or vapor sample. The reading deviations for many of the detector tubes are not more than ±25% from the true value. The long-term diffusion detector tubes operate on the principle of gaseous diffusion to give a long-term TWA measurement without a pump. The contaminant gas diffuses into the tube by means of the concentration gradient between the ambient atmosphere and the interior of the tube.

Dräger recently introduced a chemical measuring system (CMS) based on a chip, which is in effect the gas detection sensor and allows multiple measurements on one plastic carrier (Figure 16). The reactive preparation necessary for detection is kept in a hermetically sealed glass capillary until needed. The housing of the chip also protects the capillaries from potential external mechanical influences. Prelayers filter out potential interferences from other gases to ensure that the result of the measurement is substance-specific.

Figure 16 The Dräger CMS. The optical reader is shown with a chip containing 10 measurement capillaries filled with a substance-specific reagent system. (Courtesy of National Dräger, Inc.)

3.4 Ionization Detectors

General-survey instruments are used to monitor ambient conditions whenever immediate results are needed, even though the identity of the compound present may be unknown or a mixture of compounds may be present. The primary detectors used are the PIDs and FIDs. General descriptions of the fundamental theory behind their operation are available. These instruments are used for general surveying on hazardous waste sites and for industrial hygiene monitoring. They screen air, soil, water, and drum bulk samples and establish priorities for laboratory analysis. They can also be used to determine if decontamination procedures are effective. They are often used in a qualitative manner to see if volatiles are present, but they also can be used quantitatively if properly calibrated. Other applications include leak detection, perimeter monitoring, and continuous monitoring using periodic checks. Another application is boundary line sampling for total hydrocarbons to detect airborne releases to the environment from an industrial operation or hazardous waste site. All these instruments are calibrated for known gases and respond to different compounds with different levels of sensitivity. A response factor is provided with these units, but it requires that the identity of the gas to be analyzed is known.
3.4.1 Flame Ionization Detector

In a conventional FID used in GC, a gaseous sample is pyrolyzed in a hydrogen flame, producing ions and electrons. When hydrocarbons in the sample are introduced to the detection zone, ions are produced by the reaction shown in Equation (6):

$$\text{RH} + \text{O} \rightarrow \text{RHO}^+ + e^- \rightarrow \text{H}_2\text{O} + \text{CO}_2$$

(6)

where RH is the carbon compound. Ionized carbon fragments move under the influence of an electric field present between the electrodes surrounding the flame. As the positive ions are collected, a current corresponding to the collection rate is generated on the input electrode. The current is directly related to the hydrocarbon number $R$ present in the sample. The FID response is proportional to the number of carbon atoms present in the sample. Typically, the response of the FID to a C$_6$ hydrocarbon is six times the response to methane, which has only one carbon atom.

The flame ionization detector for general survey (FIDGS) is different from the FID for GC in design and performance. Instead of being mixed with the fuel and carried away to the jet, the sample is fed into the air sheath around the flame, and thus the sample reaches the flame only by a process of diffusion. This FIDGS is not selective. All hydrocarbons produce almost the same response. The basic design of the FIDGS is demonstrated by the Foxboro (East Bridgewater, MA, USA) model shown in Figure 17.

Instrument characteristics, such as sensitivity, are generally given as methane equivalents with a correcting factor. Water and carbon dioxide molecules are also present and result from the recombination of oxygen, hydrogen, and carbon molecules, but they do not affect the response of the FIDGS. This detector is insensitive to water, inert gases, and inorganic compounds and has a negligible response to carbon monoxide and carbon dioxide. It is only when the oxygen level is displaced by a high concentration of other gases that the response varies and possibly extinguishes the flame, i.e., when there is <14% oxygen.

Typically, the FIDGS has a wide dynamic range of four to five orders of magnitude, which can be expanded even further by diluting the sample. The dilution kit can also be used to enrich oxygen-deficient samples by adding ambient air that is rich in oxygen, as is modeled by Foxboro’s design.

The fuel (H$_2$) is provided in a small tank under pressure (typically several atmospheres), and oxygen is supplied from ambient air. To keep the background noise low, purified air must be used; ambient air is cleaned by drawing it through a charcoal trap and is then pumped into the detector. The sample is introduced into the ionization chamber by means of a pump.

Figure 18 shows a commercial FIDGS package from PE Photovac (Markham, Ontario, Canada). This model is hand carried and has a built-in hydrogen cylinder. The unit displays the measurement results digitally at

![Figure 17](image1.png)

* Data from PE Photovac.

Concentrations ranging from 0.1 to 50 000 ppm. The readings are displayed in parts per million of methane and require a correcting factor for other gases. The characteristics of the MicroFID from PE Photovac are given in Table 4. This instrument has an autonomy of >10 h on the same batteries and hydrogen tank. When used in combination with a PC, the MicroFID becomes a powerful sensor and complies with EPA Method 21 (fugitive emissions monitoring).

Common applications for a FIDGS include, but are not limited to, the following:

- industrial hygiene surveys and short-term health and safety monitoring;
- leak detection and fugitive emissions monitoring;
- detection of soil gases and headspace of water samples;
- detection of arson;
- solvent vapor extraction (SVE) systems in groundwater remediation.

3.4.2 Photoionization Detector

Photoionization is a flameless ionization technique. A PID consists of an ultraviolet (UV) lamp of a specific energy and an ionization chamber (Figure 19). Compounds passing through the chamber are excited by photons of UV energy from the lamp and ionized. The resulting ions are collected by an electric field; the current measured gives an accurate representation of the amount of compound present.\(^{(69)}\)

Whether a compound can be detected by a PID depends on the lamp energy and the energy required to ionize the sample (the ionization potential is the energy required to remove an electron from the sample). If the lamp energy is greater than the compound’s ionization potential, the PID will detect it.

Lamps of 9.6, 10.0, 10.6, and 11.8 eV are usually available. The 11.8-eV lamp permits the detection of many compounds, whereas the lower-energy lamps allow more selectivity, theoretically, by not responding to undesired compounds with a higher ionization potential. However, since the radiation from the UV source is not entirely monochromatic, compounds with higher ionization potentials will still be detected to some degree with lower-energy specified PID lamps as evidenced by PID/GC analysis of equal concentrations of compounds with both high and low ionization potentials.

Figure 20 shows a Model 2020 hand-held PID unit from PE Photovac. It requires compressed calibration gases. The only maintenance operations are the replacement of the water/particle inlet filter and occasional cleaning of the UV lamp. Table 5 gives the specifications of the Model 2020 PID. This PID is characterized by its small size and low weight. The operating range of the PID is limited to 2000 ppm. The PID is used for the detection of VOCs, hazardous wastes, and fugitive emissions, and all operations related to emergency response. Another application is industrial hygiene, for which it is used to monitor toxic gases and vapors in a workplace environment. The unit can operate automatically for 10 h. The internal data logger retains a complete record of the day’s activity.

3.4.3 The Foxboro Portable Toxic Organic Vapor Analyzer

The TVA-1000 is a compact portable instrument for the simultaneous analysis of organic and inorganic
compounds contained in the air (Figure 21). The instrument uses individual or concurrent PID and FID in the same package. The combination of detectors with fundamentally different responses provides unique response ratios for additional qualitative information about the analytes.

Each unit is factory-calibrated with methane (in the case of the FID) or isobutene (in the case of the PID). However, both detectors respond to many different compounds with different levels of sensitivity. To adjust the analyzer reading to the compound of interest, a correction factor must be entered into the analyzer. The result is compound-specific (corrected) readings. The specifications of the TVA-1000 are given in Table 6.

### 3.4.4 Comparison of the Flame Ionization Detector and Photoionization Detector

The FID and the PID both have advantages and disadvantages and complement rather than compete with each other. The FID has a wider operating range than does the PID (0–50000 compared with 0–2000 ppm) and is, therefore, well suited for measuring high concentrations. The FID is also less susceptible to water vapor interference than is the PID.

The PID does not require hydrogen to operate and is the detector of choice if fuel gas is limited or not available. Thus the overall PID package is typically smaller than one with an FID. It can also operate as a selective detector, depending on the ionization lamp selected. The PID is also sensitive to aromatic and chlorinated compounds and can measure some inorganic compounds that the FID does not detect at all (e.g., ammonia, carbon disulfide, arsine, phosphine, carbon tetrachloride, chloroform, ethylamine, formaldehyde, and hydrogen sulfide).

The two detectors operating simultaneously in a single instrument offer a net advantage for survey monitoring by providing information quickly about organic and inorganic vapors.

The responses of the two detectors relative to each other help identify the compounds being analyzed. For instance, the PID does not respond to methane at all, but the FID responds well. A high FID reading with virtually

The PID responds well to some inorganic gases that the FID does not detect. A high PID reading with no FID reading may suggest the presence of an inorganic compound.

4 GAS CHROMATOGRAPHY FOR ENVIRONMENTAL MEASUREMENTS

The introduction of gas–liquid chromatography in the 1950s and its subsequent enhancements coincided roughly with the increased demand for quick, reliable, and sensitive analytical methods for the determination of the many chemical compounds that contaminate the environment. GC proved invaluable for many of these applications and continues to play a major role. GC is a physical method of separation that relies on differences in solubility of components distributed between a mobile and a stationary phase. In the GC procedure of interest here, a sample is vaporized and injected into a mobile phase such as hydrogen, helium, or nitrogen and passed into a column containing the stationary (solid or liquid) phase. The components of the sample demonstrate varying affinities for the stationary phase, thus slowing (to varying degrees) their passage through the column. In the perfect case, each sample component has a different retention time in the column and is thereby separated from all others. The magnitude of the signal that each component yields as it emerges from the column and enters the detector is a measure of its concentration.

Two objectives are paramount for any analysis using GC: the data must be accurate and precise and they must be produced in a minimum of time. Sampling and separation/measurement are more important in some cases than in others. In some instances, it is more difficult to obtain a representative sample than to analyze it. GC can reduce the difficulty in obtaining a representative sample because the instrument is small enough to be brought to the field, thus eliminating errors caused by the degradation of samples during transport.

This section details some practical hints about chromatographic hardware, choice of columns, selection of injection systems, and choice and performance of detectors. Several portable gas chromatographs are described. Coupled techniques such as GC/MS are described later.

4.1 Basic Components of a Gas Chromatograph

A basic chromatograph may be extremely simple (Figure 22). It consists of a supply of carrier gas (commonly helium, nitrogen, or hydrogen) with appropriate flow regulation. In this example, the sample is introduced by means of a hypodermic syringe through a rubber septum cap into the carrier gas stream, where it is rapidly
vaporized at the head of the column before passing through the column, where it is separated. The column, in turn, is housed in a suitable temperature-controlled oven. Finally, a detector is provided to indicate when the components are eluting from the column. This detector signal, when recorded as a function of time, produces a chromatogram.

The time required for each of the components to elute is called the retention time, and the magnitude of the detector signal (peak height and peak area) depends on the amount of component present in the sample (Figure 23). In this figure, the unretained peak (usually air) is defined as $t_M$, and all other retention times are corrected from $t_M$ since this time is a characteristic of only the void volume of the column and has nothing to do with chromatography (Equation 7):

$$ t'_{R} = t_{R} - t_M \tag{7} $$

### 4.2 Classification of Gas Chromatographs Used for Field Measurements

The GC field measurement is only one part of the overall analytical procedure, which includes sample collection, sample extraction, sample concentration, sample derivatization (conversion of a chemical to another chemical), sample separation (in the separation column), and the data collection and reduction necessary to interpret the chemical information. The selection of the field instrument to be used must be based on the understanding of the complexity of the application. The instrument can be hand-portable, portable or transportable. Each type has its own features.

Portability implies that the total weight and size of the instrument are within some reasonable limits, i.e. easily carried by the average person. Versatility roughly depends on the instrument’s weight and size; the smaller the instrument, the more specialized it will be. Thus the difference between portable and nonportable gas chromatographs depends on the manufacturer’s chosen trade-offs between size and analytical capability. Analytical capability depends on the features available – type of columns, maximum temperature of the overall analytical system, type of detectors, and type of injectors. Therefore, when comparing portable gas chromatographs, it is important to understand the trade-offs that the manufacturer makes between analytical capability and portability. The analysis of gaseous samples is the simplest of field measurements, since most of the time sample preparation is not required. Hand-portable gas chromatographs fit this category and are oriented exclusively to the analysis of gases. They are light, have limited analytical capabilities (but can be sensitive), and are tailored to give a quick answer to a specific application.

A typical hand-portable gas chromatograph is a self-contained unit that includes its own gas supply and a battery pack for autonomous operation. Figure 24 shows an example of field measurement using a hand-portable instrument during an emergency situation. In this application the instrument must identify the presence of a volatile chemical without disturbing the site. No front-end sample preparation is necessary and only the vapors coming from the suspected source of contamination are analyzed. A typical analysis with a sub-parts per million sensitivity can be accomplished in a matter of minutes, but this requires some knowledge about the nature of the sample to be analyzed. There is a high probability of a miss if the hand-portable instrument is not tuned to the compound present.

The field analysis of medium/boiling-temperature volatile samples by GC is the next step of difficulty. This analysis requires that the pneumatic lines of the instrument be heated to a temperature of up to 200°C.
to avoid condensation of samples. The instrument has more features than a hand-portable instrument, but fewer than a laboratory instrument. For instance, it can accept liquid samples, and the column can be temperature-programmed to reduce the analysis time (but at the expense of the size and weight of the instrument).

Some basic sample extraction or sample preparation is also possible before analysis. The instrument can also be run directly at the field site, provided electrical power is available [alternating current (AC) line or portable power generator]. The portable gas chromatograph carries its own gas supply. Figure 25 shows the field operation of a portable gas chromatograph from HNU Systems, Inc. (Newton Highlands, MA, USA). This instrument is smaller than a laboratory instrument and can be carried by an operator in the back of a station wagon. This portable instrument provides a broader knowledge about the sample to be measured than does a hand-portable gas chromatograph, but it is bulkier and, therefore, more difficult to use for spot checks in the field.

The most elaborate and more expensive approach to quality measurements in the field is to use conventional laboratory instruments operating in a mobile laboratory. A mobile laboratory can be equipped with most of the analytical tools found in a conventional laboratory. Laboratory analytical instruments, such as gas chromatographs and mass spectrometers, are housed in commercial vehicles that have been modified to accept these instruments and to allow sample preparation. Depending on the vehicle, it can be modified to accommodate wet chemistry, analytical evaluation, and data handling at the same time. Such vehicles also provide a shelter and climate control for the operator and the equipment, and can be designed to operate in extreme weather conditions.

Figure 26 shows a mobile laboratory modified by Centrum Analytical Laboratories (Redlands, CA, USA). This van offers more than 110 ft² of laboratory space. The vehicle is air-conditioned and can provide up to 16 kVA of electrical power via diesel generators. Gas cylinder storage is provided for the transportation of compressed gases. This particular unit can accommodate a sample
preparation unit, several analytical instruments, and a computing facility, including Ethernet connections. Its full-blown version can handle gaseous, liquid, and solid samples and provide valuable field measurements with the highest-quality results. It can also be remotely connected to the outside world via wireless communication.

4.3 Categories of Analysis
Analysis can be categorized by the range of concentration of the component being analyzed—major components (5–10%), minor components (100 ppm–5%), and trace analysis (1 ppb–100 ppm). Only the last category will be considered. Trace analysis for which the sample concentration is <100 ppm is certainly the most difficult to perform and is routinely required for environmental analysis. Methods of trace analysis require the highest level of instrumentation sensitivity and sample preparation to enhance the concentration level of the analyte. Analytical procedures for air or gaseous sample matrices are required for three types of analysis: air emission methods for stationary or point sources such as incinerators, power plants, and various industrial processes; ambient air monitoring methods; and methods for monitoring indoor air contamination in the workplace. Air emissions and ambient air monitoring fall within the jurisdiction of state agencies and several offices of the USEPA. Indoor air monitoring falls into the realm of industrial hygiene monitored by OSHA. The basic principles for the sample preparation and analysis of industrial hygiene samples are the same as those applied to outdoor air pollution.\(^{71}\)

4.4 Trace Analysis of Gaseous Samples
With the sophisticated analytical instruments available, it is easy to lose sight of the importance of sample preparation techniques. Even the most powerful of the analytical instruments will be useless with a sample that is improperly collected or prepared.

Gases and vapors diffuse rapidly, mix freely with the general atmosphere, and can reach equilibrium in a short time. They therefore offer fewer difficulties in air sampling than do aerosols. For air sampling purposes, contaminants can be grouped with respect to solubility and vapor pressure. Many gases and vapors of hygienic significance are water-soluble and can be collected in aqueous media with or without a dissolved reacting chemical to suppress the vapor pressure of the solute. Gases and vapors that are not water-soluble but are soluble or reactive in other agents can be adsorbed in a suitable solvent. Gases and vapors that are neither soluble nor reactive may be collected on adsorbent (e.g. activated charcoal, silica gel, or molecular sieves) in either active or diffusive (passive) samplers. Adsorbents have become the sample collection medium of choice for all gases and vapors because of their convenience and generally high collection efficiency.

As indicated previously, analysis is the final step of a complex process that depends on the nature of the sample, the matrix in which the sample is found, the level of concentration of the sample, and the availability of a field instrument. In the most general case, the steps preceding analysis are identified as sample collection, sample concentration, sample extraction, and sample derivatization. It is only after all or some of these steps are completed that the sample can be analyzed. Sample collection can be accomplished just before the analysis by drawing the sample through a sampling line connected to the gas chromatograph. The probe itself can be the gas chromatograph.\(^{72}\) Tedlar bags or appropriate containers (glass or inert metal) can also be used to collect samples that are then transported to a laboratory for analysis. The use of evacuated stainless-steel canisters to sample VOCs is a standard procedure in the industry.\(^{73}\) These approaches are applicable to clean samples, such as hydrocarbons in air. The drawback of sample storage is the risk of sample degradation, either by adsorption on the walls of the container or by selective adsorption in the trap, creating a change in the relative concentration of the compounds present in the sample.

When the sample is part of a complex matrix, whether gaseous, liquid, or solid, the extraction stage consists of isolating the vapor sample from its matrix. This extraction stage is usually accomplished thermally (headspace, purge and trap, thermal desorber, pyrolyzer). It is seldom done directly at the collection point, since extraction equipment is not readily transportable to the field. Care should be taken in evaluating the analysis as the extraction process can degrade the sample and introduce a bias.

Solid adsorbents are useful for trapping a gaseous sample before analysis. This trapping approach also offers the advantage of concentrating the sample at the time it is stored, by passing a known quantity of air through the adsorbent and retaining only the sample of interest. The analyte collected on a solid adsorbent can then be desorbed with an organic solvent. This sample-rich solvent can then subsequently be injected into the gas chromatograph. The analyte may also be concentrated by partitioning it into a liquid phase coated on a support material. Impingers can be used to concentrate analytes in a gaseous matrix by passing the sample through an appropriate solvent that retains the analytes but allows the gas to escape. The solvent can be further concentrated or injected directly into the gas chromatograph. The adsorption is usually sample- and volume-dependent. All these devices must be carefully prepared for the samples of interest when quantitative measurements are performed. Sorbents and impingers were reviewed earlier; solid adsorbents have been described in the literature.\(^{74}\)
Derivatization is an additional preparation step that is used less frequently. It consists of chemically converting an analyte into another chemical species to improve stability, sensitivity, or instrument performance. One popular application of derivatization techniques is to convert a compound that does not respond to an electron capture detector (ECD) into a product with electronegative properties and a favorable ECD response. Another example of derivatization is the conversion of carbon monoxide or carbon dioxide to methane before introduction to the FID.

The following general discussion considers aspects of sample preparation procedures so that the analyst can evaluate practical applications and identify the logic behind the various modifications to the procedures.

### 4.5 Solid Extraction Thermal Desorber Unit

The use of solid sorbent sampling is illustrated with an application of a field-operable unit for VOC analysis, developed by Louisiana State University. The unit includes two traps and provides an enrichment factor up to 1000:1. The first trap provides the concentration of analytes on a large breakthrough trap (the concentration trap), desorption of analytes on a low volume desorption plug trap (the focusing trap), desorption of analytes into the analyzer instrument in a narrow plug, and back-flushing of the system between analyses to prevent cross-contamination.

Figure 27 illustrates the VOC sample processing device. The concentrating trap can be exposed to large volumes of gases, up to 2 L, on a low thermal mass concentrating trap packed with hydrophobic adsorbents. Breakthrough volumes are, of course, compound-dependent, but with dual-bed series, packed traps are typically in the 1–2 L range for common VOC analytes when using Tenax® and carbon molecular sieve adsorbents. Water in the sample is not significantly retained by these sorbents, and thus its concentration is reduced in the extracts. Since the desorption plug from the concentrating trap is several milliliters in volume (typically 5–10 mL), the analytes in this plug are recombined on a small and low thermal mass focusing trap into a final volume of approximately 300 µL. This small concentrated plug of analytes, typically 1 µL and generally devoid of large quantities of water, is then passed to an appropriate analyzer for qualitative and quantitative determinations.

The unit manufactured by Analytical Specialists Inc. (Baton Rouge, LA, USA) is microprocessor-controlled and can be operated remotely. The total amount of power necessary to operate the unit and desorb the samples from the traps is approximately 50 W. Furthermore, since it is a dual-trap system, selective adsorbent chemistry can be used to enhance performance in special applications.

### 4.6 Transfer Lines

The use of fluidic (no moving mechanical parts) sampling and column-switching valves in GC has been reviewed. Enviroprobe, the air probe developed by the University of Utah and commercialized by FemtoScan (Salt Lake City, UT, USA), is an example of this approach (Figure 28). The Enviroprobe operates with a small vacuum pump and provides the functions of collection, injection (from 20 ms), and separation [column of 100 µm inner diameter (ID), 1 m long]. The unit output is connected to another analytical instrument, here a portable mass spectrometer.

### 4.7 Airborne Pollutants

Ash or fly ash, the solid debris that remains after incineration processes, is another class of solid sample material that is of environmental concern. These airborne and potentially carbonaceous particles contribute to visibility reduction and have complex chemical compositions that include carcinogenic and mutagenic organic compounds. The chemical composition and structure of particle organic matter can provide important information regarding origin, distribution, and fate of respirable aerosols of small dimensions (typically 10 µm). Although current regulations for these types of small particle matter (PM10) are concerned only with total particle densities over a period of time (typically 24 h), future regulations must address the obvious link between their chemical composition (e.g. heavy metal, carcinogen, or allergen content) and associated health risks. Permits for PM10...
emissions for specific particles must be obtained from the USEPA. Another subset of particle matter is PM$_{2.5}$, particles with mean aerodynamic diameters $< 2.5 \, \mu m$. The USEPA is considering adding a PM$_{2.5}$ standard, primarily to protect vision.

Numerous organic compounds may be adsorbed on particles as they enter the atmosphere and contribute to air, soil, and water pollution. These organic compounds are difficult to extract from particulate airborne pollutants.

Many of the same compounds that must be determined in soil and water samples must also be determined in airborne pollutants. The major procedural difference required for the analysis of air samples is concerned with the collection of the sample itself. The GC portion of the analysis for a given class or group of compounds is essentially the same as that described for the analysis of extracts prepared from soil and water samples.

4.8 Collection and Analysis of Airborne Pollutants

Methods for particle collection and separation are still empirical. A field procedure will be used as an example of a fieldable system that encompasses sample collection, sample transfer, and sample analysis units, including a gas chromatograph and a mass spectrometer operating in a mobile laboratory unit.

Atmospheric particles with an aerodynamic diameter $< 10 \, \mu m$ (PM$_{10}$) are obtained by drawing an aerosol through an impaction jet and depositing larger particles on a plate immediately in front of the nozzle. The impactor is contained in a stainless-steel delivery tube to channel the air flow to a filter holder and a particle counter. Particles are collected in a clean filter. The sampling port is raised approximately 1.5 m (5 ft) above the roof of a transportable laboratory module (Figure 29).

Aerosol concentration and particle-size distribution measurements (parallel to aerosol collection on quartz fiber filters) are performed at 10-min intervals over eight size-resolved channels covering the 0.3–10-\(\mu\)m diameter range using a multichannel particle counter.

Samples are positioned inside a special glass reaction tube lined with a ferromagnetic foil. VOCs and SVOCs are desorbed by flash desorption at a temperature of 315°C and nonvolatile organic matter is pyrolyzed with a Curie-point desorption–pyrolysis reactor at a
Figure 30 Schematic representation of the PM$_{10}$ (aerosol) and VOC (vapor) sampling modules and the desorption GC/MS system used for analyses.\textsuperscript{82}

temperature of 650 °C. A schematic representation of the unit is shown in Figure 30.

Volatile analytes from the reactor are transferred into the mass analyzer via a short capillary column (transfer line) that can be temperature-programmed up to 20 °C/s. The capillary is inserted into the ion trap mass spectrometer.

4.9 Theory of Packed and Fused-silica Capillary Column Operation

The introduction of inert fused-silica columns markedly changed the practice of GC, allowing high-resolution chromatography in most laboratories. A further decrease in the use of packed columns occurred after the introduction of megabore capillary columns of 0.53 mm ID that, with their increased sample capacity, served as direct replacements for the packed column. These developments, in conjunction with the emergence of immobilized or cross-linked stationary phases especially tailored for fused-silica capillary columns, have been responsible for the greater acceptance of capillary GC.

The use of packed columns represents 20% of GC analysis for laboratory applications. The percentage is even smaller for field applications. Packed columns are employed primarily for preparative applications, for fixed gas analysis, and in those separations for which high resolution is not always desirable. Packed columns will continue to be used for GC methods that were previously validated on packed columns and for which the time and cost of revalidation on capillary columns would be prohibitive.

The introduction of commercially available fused-silica capillary columns in late 1979 followed an investigation of the applicability of fused silica in fiber-optic technology to chromatographic columns.\textsuperscript{82} The inherent strength and flexibility of fused silica make it easier to use and less fragile than silicate glass capillary columns. In addition, fused silica provides a more inert surface for improved capillary performance and less adsorption of active components.

Uncoated fused-silica capillary tubing is susceptible to moisture in the air. Water molecules attack the silic–oxygen bonds, forming silanol groups and opening cracks that propagate into fractures. Protecting the silica from moisture and scratches is the main reason for the outer coating of either polyimide or some other equally resistant material.

A good understanding of the use of capillary columns begins with an understanding of the terminology. Perhaps the most important terms to become familiar with are selectivity, resolution, and efficiency. Further information on the theory of capillary GC and its practical implications can be found in the literature.\textsuperscript{66,67,83}

4.9.1 Column Selectivity

The critical step in developing a GC method is the selection of a stationary phase for which each sample component has a different affinity, thus ensuring a separation in the column. Analysis on a large number of
phases has been reported through the years and has been reviewed in the literature.\textsuperscript{(84,85)} By far the best method for classifying stationary phases was introduced in 1966\textsuperscript{(86)} and later modified.\textsuperscript{(87)} In this procedure a group of compounds (benzene, butanol, 2-pentanone, nitropropane, and pyridine) containing different functional groups are chromatographed on the phase to be classified, and their Kováts retention indices $I$ are recorded. The differences in the indices for the compounds from those recorded on the squalane stationary phases are the Rohrschneider indices for that phase and are a measure of the phase’s selectivity to the particular functional group contained in the probes. For the probes listed in Table 7\textsuperscript{(66)} the constants are denoted by $x'$, $y'$, $z'$, $u'$, and $s'$. Some of the more popular phases, along with their modified Rohrschneider indices, are listed in the table. It should be noted that a casual inspection quickly reveals that there is no significant difference in the selectivities of the older SE-30 phase and the newer highly purified methylsiloxane OV-1.

### 4.9.2 Kováts Retention Indices

A uniform expression for retention data that is relatively free of instrumental contribution is given by the Kováts retention index system.\textsuperscript{(68)}

The retention index $I$ of a compound is descriptive of its elution position between two saturated hydrocarbons. The retention index of an $n$-alkane is assigned a value equal to 100 times its carbon number. Thus, for instance, the $I$ values of $n$-octane, $n$-decane, and $n$-dodecane are 800, 1000, and 1200, respectively; by definition, they are applicable to any column (packed or capillary) and any liquid phase and are independent of every chromatographic condition, including column temperature. For all compounds other than $n$-alkanes, the chromatographic conditions, such as the stationary phase, film thickness, and column temperature, must be specified.

The $I$ value of a component can be determined by spiking a mixture of $n$-alkanes with the component(s) of interest and analyzing the resulting mixture via chromatography under specific conditions. A plot of log-adjusted retention times versus retention indices is generated, and the retention index of the solute under consideration is determined by extrapolation. To eliminate graphical errors, the retention index of an analyte $a$ at an isothermal column temperature and for a stationary phase $S$ can be calculated from Equation (8):

$$I_a^S = 100N + 100n \left( \frac{\log t'_{R,a} - \log t'_{R,N}}{\log t'_{R,(N+n)} - \log t'_{R,N}} \right)$$

where $t'_{R,a}$ is the adjusted retention time of the component under consideration, $t'_{R,N}$ is the adjusted retention time of the $n$-alkane eluting before the component, $t'_{R,(N+n)}$ is the adjusted retention time of the $n$-alkane eluting after the component, and $N$ is the carbon number of the $n$-alkane with retention $t'_{R,N}$.

The concept of a retention index has been extended to programmed GC.\textsuperscript{(89)} The calculation of temperature-programmed $I$ values, as shown in Equation (9), involves a linear function of unadjusted retention times rather than the logarithmic function used to calculate isothermal $I$ values. The temperature-programmed index of analyte $a$ on liquid phase $S$ and at temperature program $p$ is given by Equation (9):

$$I^S_{a,p} = 100N + 100n \left( \frac{t'_{R,a} - t'_{R,N}}{t'_{R,(N+n)} - t'_{R,N}} \right)$$

where $t'_{R,a}$, $t'_{R,N}$, and $t'_{R,(N+n)}$ are the retention temperatures of the component and the $n$-alkanes that bracket the component. Retention indices normalize instrumental variables in gas chromatographs, allowing retention data generated on different systems to be compared. Libraries of Kováts indices for large numbers of compounds on different liquid phases (polar and nonpolar) are available and allow the chromatographer to identify unknown compounds rapidly.\textsuperscript{(90)} The dual-column approach permits the simultaneous gathering of data on two stationary-phase columns of different polarities. One advantage of this approach is greater confidence in the identification, since compounds that co-elute on one of the columns may well be separated on the other.

### 4.9.3 Relative Retention and Selectivity

Relative retention $\alpha$ is a measure of the selectivity of the column. It is defined as the ratio of adjusted retention times (Equation 10):

$$\alpha = \frac{t'_{R,j}}{t'_{R,j}}$$

where $t'_{R,j} > t'_{R,i}$. The selectivity factor $\alpha$ is a measure of the physicochemical interactions between the solutes and the stationary phase.
In the older literature, retention was reported as relative retention with respect to some arbitrary standard. However, it is much more sensitive to a number of variables, such as temperature and flow rate, than is the Kováts retention index and has been abandoned as a reporting tool. However, it is still being used as the selectivity variable in the second critical step of designing a chromatographic method, i.e. calculation of the necessary length needed for a given separation.

In capillary chromatography, another measure of column separation power is the separation number, or Trennzahl (TZ). The Trennzahl is defined as the resolution of two consecutive members of a homologous series differing by one methylene unit. The Trennzahl is related to resolution $R$ by Equation (11):

$$TZ = \frac{R}{1.177} - 1$$  \hspace{1cm} (11)

Practically, the separation number is a measure of the number of peaks that could be separated between the two consecutive homologs, or the effective peak number. The calculation of Trennzahl is illustrated in Figure 31(a) and (b). The separation number for the capillary column calculated from the $C_{12}$ and $C_{13}$ alkanes is more than three times greater than that for the packed column. The capillary column is capable of resolving 21 peaks between $C_{12}$ and $C_{13}$, the packed column only six.

4.9.4 Column Efficiency

The simplest form of the fundamental equation underlying the relationship between $h$ as a function of the longitudinal diffusion and its resistance to mass transfer at low mobile phase velocities is often referred to as the Golog equation\(^1\) (Equation 12):

$$h = \frac{B}{\mu} + C\bar{\mu}$$  \hspace{1cm} (12)

where $h$ is the column efficiency or height equivalent to a theoretical plate (HETP), $B$ is the contribution to plate width due to longitudinal diffusion of the solute in the gas phase, $C$ is the contribution to plate width due to resistance in mass transfer of the solute between the mobile and stationary phase, and $\bar{\mu}$ is the average linear velocity of the mobile phase. An expanded form of this equation that includes terms for the resistance to mass transfer from the gas phase and extra column contributions is available.\(^6\) Longitudinal diffusion is always present and acts to broaden the solute peak the longer the component stays in the column. Resistance to mass transfer is a function of the partition ratio $k$ and describes the diffusion of a component into and out of the stationary liquid phase.

A measure of the solute plug broadening as it travels the length of the column is defined in terms of the solute retention time and the standard deviation of the chromatographic peak, as the theoretical plate number $n$. It can be calculated by Equation (13):

$$n = \frac{t_R}{\sigma}$$  \hspace{1cm} (13)

where $t_R$ is the retention time and $\sigma$ is the standard deviation of the peak.

Column efficiency $h$ is usually normalized to column length, $n/L$. The efficiency of a column can also be expressed as the relationship of the HETP, $h$. This is a measure in millimeters of the column length occupied by one theoretical plate (Equation 14):

$$h = \frac{L}{n}$$  \hspace{1cm} (14)

For a wall-coated open-tubular (WCOT) capillary column, the minimum theoretical efficiency attainable $h_{\text{min}}$
is given by Equation (15):

\[ h_{\text{min}} = \frac{1 + 6k + 11k^2}{3(1 + k)^2} \]  

(15)

where \( k \) is the capacity factor. This is the theoretical column efficiency obtained for perfect stationary phase coating under ideal conditions. Many manufacturers, as a measure of their column coating efficiency, compare the calculated value with that obtained experimentally on their column.

4.9.5 Column Resolution

The decision as to what resolution is required is an arbitrary one and in the hands of the analyst. Once a number has been picked for the resolution, the problem then revolves around the following questions: how many plates are needed to achieve this resolution? and how long a column is needed to obtain the required number of plates? A quantitative expression for the degree of peak separation is Equation (16):

\[ R = \frac{2(t_{R,j} - t_{R,i})}{w_{b,j} + w_{b,i}} \]  

(16)

where \( R \) is the resolution, \( t_{R} \) is the retention time of components \( i \) and \( j \), and \( w_{b} \) is the peak width at the baseline. A resolution of 1.5 gives essentially baseline resolution of symmetrical peaks of equal height.

4.9.6 Length of Column Required for Separation

The number of plates required for a given resolution of two solutes was derived as follows according to Equation (17):

\[ n = 16R^2 \frac{\alpha}{\alpha - 1} \frac{k + 1}{k} \]  

(17)

Thus the required column length is given by Equation (18):

\[ L_{\text{reqd}} = h_{\text{reqd}} \]  

(18)

Unfortunately, the prediction of an experimentally obtainable value of \( h \) is not very easy, and the application of Equation (18) is therefore not as simple as it appears.

4.10 Parameters Influencing a Separation

The major factors that influence \( h \), and thus the required column length, are a function of several interrelated column, extracolumn, and operational parameters. Major factors that influence column efficiency are column ID, column length, the type of stationary phase and its film thickness, the type of carrier gas, the carrier gas velocity, and the column temperature, in addition to other instrumental limitations, such as the sample injection width, dead volumes between injector and column and detector, detector volume, data acquisition time constants, and data rates.

Fortunately, a computer model is now available that not only computes \( L_{\text{reqd}} \) from the inputted values of the column and instrument variables, the identity of the stationary phase, and the Kováts indices of the sample components, but also generates the predicted chromatogram. Use of such a program saves invaluable laboratory method development time. Examples of computer-aided column selection and optimization are described later.

4.10.1 Choice of Carrier Gas

Profiles of \( h \) versus \( u \) for three carrier gases with a thin-film capillary column are displayed in Figure 32. The greatest efficiency is obtained with nitrogen at a lower linear velocity, but speed of analysis must be sacrificed. The increasing portion of the curve is steeper for nitrogen, meaning that efficiency and resolution drop quickly when working off \( u_{\text{opt}} \). On the other hand, for a slight loss in the number of theoretical plates, a reduced analysis time is possible with helium and hydrogen, because \( u_{\text{opt}} \) occurs at a higher linear velocity. Moreover, the mass transfer contribution or rising portion of a curve is less steep with helium or hydrogen, which permits working over a wider range of linear velocities without a substantial sacrifice of resolution.

When comparing these carrier gases at a linear velocity corresponding to equal values of plate height, note that the lighter carrier gas (H\(_2\)) can elute solutes at
lower temperatures during temperature programming with narrower band profiles, since higher velocities can be used. Thus hydrogen or helium is recommended over nitrogen as a carrier gas.

The effect of the carrier gas on chromatographic resolution is illustrated in Figure 33, in which the flow is slightly off the optimum. The greatest efficiency (the minimal HETP) is obtained with nitrogen; however, this minimal value occurs only over a narrow range of carrier gas velocities with its efficiency decreasing sharply with increasing average linear velocity.

4.10.2 Effect of Column Temperature on Separation

Column temperature has a dramatic effect on separation. The logarithm of the capacity factor \( k \) is inversely proportional to the temperature. The lower the column temperature, the greater is the capacity factor, thus increasing the time that the component spends in the stationary liquid phase. Increased retention in the stationary liquid phase allows greater advantage to be taken of the selective properties of that stationary phase. However, the chromatographer should be aware that, as a result of this selectivity change due to temperature, large changes in retention can occur that, in some cases, change the order of the elution.

4.10.3 Stationary Phase Film Thickness and Column Internal Diameter

Changes in either the stationary phase film thickness or the column ID change the phase ratio \( \beta \), and greatly influence the capacity factor. An increase in film thickness (or decrease in the phase ratio) results in an increase in the capacity factor and, therefore, increases in component retention and resolution. This is illustrated in the analysis of gasoline shown in Figure 34. Increased resolution, however, is accompanied by a dramatic increase in analysis time.\(^{96}\)

Analysis time, measured as the retention time of the last eluting peak from a column of length \( L \), is given by Equation (19):

\[
t_R = L \left( \frac{1 + k_x}{\bar{u}} \right)
\]

where \( k_x \) is the capacity factor of the last-eluting peak. The capacity factor is given by Equation (20):

\[
k_x = \frac{t_{R,x} - t_M}{t_M}
\]

where \( t_M \) is the retention time of an unretained compound (such as air) and \( \bar{u} \) is the average linear velocity of the mobile phase. Reducing the column length will decrease the analysis time at the expense of resolution (since \( n \) is decreased). This may not be a severe handicap, since most chromatographic separations do not require baseline separation. Column temperature has a dramatic effect on separation. The logarithm of \( k \) is inversely proportional

**Figure 33** Effect of carrier gas on the resolution of \( n \)-heptadecane and pristane. (Courtesy of Agilent Technologies.)

**Figure 34** Analysis of gasoline on columns with varying stationary phase film thicknesses.\(^{96}\)
to the temperature. The lower the temperature, the greater is the capacity factor, thus increasing the time that the component spends in the stationary liquid phase. Reducing the ID of the column increases the efficiency and resolution of the separation but reduces the sample capacity.

4.10.3.1 Sample Capacity Sample capacity is the ability of the column to tolerate high concentrations of solute. Degradation of chromatographic performance is seen when the column capacity is exceeded. This situation is commonly referred to as overload and is indicated by peak broadening and asymmetry as shown in Figure 35. The relationships between sample capacity, film thickness, and phase ratio are shown in Figure 36 as log plots of film thickness versus phase ratio and sample capacity relative to a 250-µm ID column with a 1-µm film. These curves are for the commonly used commercial FSWCOT column of ID between 50 and 530 µm. By extrapolating the appropriate curve for the desired column diameter and film thickness, both the phase ratio of the column and the sample capacity can be determined. For example, a 3-µm film on a 530-µm ID column (phase ratio of 45) has 5.5 times the sample capacity of the 250-µm ID column.

4.10.4 Fast Capillary Gas Chromatography

A major trend in GC in recent years has been fast separations using small-bore columns. The advantages of high-speed capillary GC (HSGC) are the ability to separate high boiling points within a relatively short time, to achieve higher resolution, to study the separate effect of each of these parameters and to optimize all the conditions simultaneously with a minimum of experimental chromatographic work. The operator defines the simulated runs with parameters similar to those used with a gas chromatograph, but

Using currently available instrumentation have been published.[98]

Several papers have discussed the advantages and disadvantages of narrow-bore WCOT columns for high-speed capillary GC.[99–101] For HSGC without significant loss in resolution, it has been recommended that the column ID should be reduced to 0.1 mm or less. However, in many cases there is no advantage to using 0.1-mm ID columns over an optimized operation of the more conventional 0.25-mm ID column.[94] The most serious limitations to the use of reduced-diameter columns are associated not only with sample capacity but also with the various limitations of current instrumentation.

Within the limits of current instrumentation, 100-µm ID columns of 5–10 m length can be operated with minor modifications.

4.11 Computer Optimization of the Separation

Chromatographic separation optimization can be broken into two major areas: stationary phase selection and optimization of the analysis conditions. Several tools are now available to aid the chromatographer in making a decision with few or no laboratory experiments. Pro ezGC (Analytical Innovations, Inc., Kettering, OH, USA) and Dry Lab (LC Resources, Walnut Creek, CA, USA) are models that use the temperature and pressure programming approach to GC analysis. OnLine’s (Duxbury, MA, USA) GC Lab is an isothermal model that uses the appropriate lengths of serially coupled columns containing the stationary phase of widely different selectivities. One example using Pro ezGC to optimize the run time on a given liquid phase is given below.

In the following computer-aided optimization example, Pro ezGC is used to optimize the temperature separation of the mixture of 20 phenols and pesticides on cross-linked 5% phenylmethyl siloxane DB-5. The list of the components is given in Table 8. The first simulation shown in Figure 37(a) and (b) was run with a hypothetical column of 60 m × 0.25 mm ID × 0.25 µm film thickness coated with DB-5. An arbitrary temperature of 100 °C and a flow velocity of 45 cm s⁻¹ hydrogen were used. This run was isothermal with no attempt to optimize the separation.

Obviously, it is not necessary to be a chromatographic expert to see that the total run time can be shortened considerably by programming the column temperature, by shortening the column, and by selecting another flow velocity. Program simulation gives the user the capability to study the separate effect of each of these parameters and to optimize all the conditions simultaneously with a minimum of experimental chromatographic work. The operator defines the simulated runs with parameters similar to those used with a gas chromatograph, but

![Figure 35](https://via.placeholder.com/150)

**Figure 35** Peak shape of (A) dodecanol and (B) n-pentadecane with increasing amounts of sample on the column. Column: 10 m × 0.10 mm × 0.17 mm cross-linked fused-silica wall-coated open-tubular (FSWCOT). Sample capacity is reached at 8 ng/component.[92] (Courtesy of Agilent Technologies.)
yielding the tremendous advantage of obtaining the results in minutes instead of days.

The boundary conditions of the simulation are as follows:

Length of column: 7.5, 15, 30, and 60 m
Liquid phase: DB-5
Flow velocity: 45–120 cm s⁻¹, in increments of 15 cm s⁻¹
Initial temperature: 100–200 °C, in increments of 25 °C
Temperature programming conditions: 5–45 °C min⁻¹, in increments of 5 °C min⁻¹
Final temperature: 300 °C

This range of conditions requires 1080 simulations, which are performed in just a few seconds on a laptop computer.

The optimized conditions of the run are as follows:

Resolution: 1.5
Column: 15 m × 0.25 mm ID × 0.25 μm film thickness, DB-5
Initial temperature: 150 °C
Temperature rate: 30 °C min⁻¹ up to 300 °C
Inlet pressure: 54.6 kPa (8 psi)

Figure 37 shows the results of this optimization. The total separation for the baseline resolution is done in <4 min. There are applications for which baseline separation is not necessary.

By accepting a minimal resolution of 0.8 instead of 1.5, the shorter calculated run time could be reduced by 50% (<2 min). No attempt was made to shorten this separation any further.

4.11.1 General Comments

The computer tools that are now available, although currently limited to gas–liquid applications, offer the tremendous potential for operating gas chromatographs much more efficiently using less skilled personnel. A program such as Pro ezGC aids the analyst in minimizing run time by optimizing the programming conditions of flow and temperature. The GC Lab simulation tool gives the user the capability of optimizing the overall selectivity of the column (probably the most important step in method development) by optimizing the selectivity of two independent segments of column individually coated with different liquid phases. Also, optimization may be focused either on designing for minimal time analysis or minimum detection limits. Most of the simulation programs allow for the addition of compounds to the library, either through in-house laboratory work or by purchasing commercial libraries containing many compounds in a variety of stationary phases.

The simulation tools allow the analyst to experiment with various methods, in essence developing a GC method at the computer keyboard. The parameters of the proposed method are obtained quickly and can then be used to design the proper laboratory experiments for its validation. All of this saves the valuable laboratory time normally required in the initial method development stage. The experimental results, however, are only as good as the chromatographic model that is used to predict them. In the case of fast chromatography, for instance, the dead volumes upstream and downstream of the column contribute to peak broadening, and accurate quantitative analysis is sacrificed as peak widths decrease below the minimum of 20 points per peak needed for accurate and precise quantitative determination. One of the simulation tools (GC Lab) allows for user inputs of these extra column contributions. It has been verified that when this is done, the predicted chromatograms generated with the model match those obtained in the laboratory.\(^{(102,103)}\)

As with all automated tools, the user should be conscious of their limitations, regarding them as somewhat imperfect mathematical tools. It is only by iteratively correcting to the model using results obtained in the laboratory that accurate predictions of experimental results are generated by the computer.

4.12 Sample Injection Devices

The main function of a GC inlet is to provide the accurate, reproducible, and predictable introduction of a sample into the column. The sample can be gaseous, liquid, or solid, and several injection modes can be used. There is no single inlet that can satisfy all analytical requirements.
Inlets are usually divided into packed-column inlets and capillary-column inlets. Sample introduction has been discussed at length in the literature. Inlets must be selected carefully for each analysis and used to optimize chromatographic efficiency, analytical accuracy, and the reproducibility of results. Because capillary columns have higher efficiency and lower sample capacities than do packed columns, inlet performance is much more vital to obtaining accurate results with capillary rather than with packed-column systems. Once an inlet has been selected based on sample, column type, and analysis goals, all inlet variables must be set appropriately to achieve optimal results. The type of analysis and the composition of the sample itself are the primary factors that must be considered when setting or determining the interrelated variables related to the injection itself (type of injector, injected volume, injection temperature) and to the chromatographic analysis (column selection and column temperature).

4.12.1 Effect of Inlet on Peak Broadening

A basic functional requirement of GC inlets is that they introduce the sample into the column as a narrow band with a composition that is identical with that of the original sample. The inlet should produce peaks (width-of-injection function) that are much narrower than the expected peak width resulting from the column band-broadening process. More efficient columns require narrower initial peak widths. This can be accomplished by using inlets that generate narrow peaks initially, or by using subsequent focusing techniques. Initial bandwidths are broadened by band broadening in time or by band broadening in space. Band broadening in time is caused by the slow transfer of sample vapor from the inlet to the column. The initial peak width is equal to the time it takes for the sample to be transferred to the column. Band broadening in space is a direct consequence of the migration and spreading of a liquid sample within the column, either after the cool on-column injection of the sample into the column or after recondensation of the sample in the column. The condensed liquid, which starts by occupying only a few centimeters of column, becomes too thick to be stable and spreads over a greater length of column. The carrier gas pushes the plug further into the column, creating a flooded zone. The solute material is spread over the full length of the flooded zone, creating an initial peak width that equals the length of the flooded zone.

4.12.2 Sample Focusing as a Way to Reduce Peak Broadening

Several focusing techniques are used to narrow peak broadening in time and space: stationary phase focusing, solvent focusing, thermal focusing, and retention gap.

4.12.2.1 Stationary Phase Focusing

Stationary phase focusing is the most frequently used focusing technique and is possible only in temperature-programmed analysis. Retention times of solutes are an exponential function of temperature. As the initial temperature of the column is lowered, the speed at which solutes travel down the column slows drastically. As a vaporized sample moves from the inlet to the column, it comes in contact with the stationary phase and is trapped in a narrow zone. The lower the temperature, the more effective the focusing.

4.12.2.2 Solvent Focusing

As the condensed solvent starts to evaporate, solutes with volatility similar to that of the solvent tend to concentrate and focus on the solvent tail. This solvent focusing, or the “solvent effect”, yields narrow peaks for these early-eluting compounds, as shown in Figure 38.

4.12.2.3 Thermal Focusing

Thermal focusing relies on the condensation of gases in a tube or at the head of the column. Peaks narrow as the solute volume is reduced during condensation. Solutes do not migrate into the chromatographic system until the temperature is raised, then they are vaporized again.

Sometimes cryogenic temperatures (cryogenic focusing) are used to focus peaks from inlets or auxiliary sampling devices that generate peaks broadened in time. Thermal focusing narrows bandwidths effectively only when the column temperature is approximately 150 °C below the boiling points of the solutes. In this sense, thermal focusing does not rely on chromatographic processes. It requires only a surface on which vapors can condense.

![Figure 38](http://example.com/figure38.png) The solvent effect. (Copyright 1997, Agilent Technologies. Reproduced with permission.)
4.12.2.4 Retention Gap  A retention gap is an empty piece of column that accommodates the condensed sample but does not retain solvent or solutes once they have been vaporized. The primary function of the retention gap is to reduce the length of the flooded zone created whenever solvent is condensed in the column. An equally important function is to protect the column from nonvolatile sample components, especially when doing cool on-column injection (Figure 39).

4.13 Types of Capillary-column Inlets

Capillary-column inlets that use hypodermic syringes to introduce the samples fall into two categories: vaporizing and nonvaporizing (cold) injections.\(^\text{(105)}\)

4.13.1 Vaporizing

Capillary direct, or vaporizing, injections are used with some capillary columns of ID > 0.5 mm and are made by substituting a special insert inside a packed-column inlet to protect the column from nonvolatile sample components.

Split mode injection uses a vaporizing inlet that vents most of the sample in the split mode and transfers most of it to the column in the splitless mode. It is also column protecting but can cause discrimination and decomposition of the sample. Split injection is used for general analysis, whereas splitless injection is most frequently used for trace analysis.

The programmed temperature vaporizer (PTV) inlet offers a mixture of injection possibilities, including cool sample introduction, split or splitless modes, and sample concentration (solvent elimination mode); it is column protecting. Because of this flexibility, PTV inlets are useful for both general and trace analyses.

![Figure 39 Visual representation of on-column injection into a retention gap. Both solvent and stationary phase focusing occur.](Copyright 1997, Agilent Technologies. Reproduced with permission.)

4.13.2 Nonvaporizing

Cool on-column inlets give high accuracy and reproducibility, do not lead to sample decomposition, have the least solute discrimination among all the inlets, and work by depositing the sample directly into the column. Unlike vaporizing sample introduction techniques, here the sample is not exposed to high temperatures during injection or transfer to the column. Cool on-column inlets are used for the analysis of samples with a wide boiling-point range or those that are thermally sensitive for trace analysis.

4.13.3 Types of Capillary-column Inlets Using Mechanisms Other than Syringes

Other sample introduction devices include gas and liquid sampling valves, headspace autosamplers, thermal desorbers, purge-and-trap samplers, pyrolyzers, and transfer lines. Depending on the sampling device and the GC column used, auxiliary sampling devices can be connected directly to the column or to an existing inlet.

4.13.3.1 Valves

Valves can consistently introduce fixed volumes of gas or liquid samples and are simple to automate. Valves are versatile, can operate at elevated temperatures (several hundred degrees), have a fast response time (down to fractions of a second), and can be small enough to be mounted into a portable instrument. Valves are frequently used for sampling gases and liquids in moving streams (process and on-line monitoring).

4.13.3.2 Sample Introduction Based on Gas–Liquid Extraction

The principle of sample introduction based on a gas–liquid extraction is fairly simple. Once an equilibrium has been achieved, an analyte distributes itself between two immiscible phases (here the gas and the liquid sample phases) at some constant ratio. The two modes of gas–liquid extraction are static and dynamic. In the static mode, the analysis begins with the addition of an accurate volume of sample into the vial. The sample volume must be selected to allow for the appropriate volume of gas phase or headspace in the remaining volume of the vial.

In the dynamic or purge-and-trap mode, extraction of the sample is effected by passing a constant flow of gas through the aqueous sample. The analytes are continuously purged from the sample and carried by the gas flow to a medium that can collect and concentrate the analytes.

4.13.3.3 Microextraction

Microextraction has been shown to be an efficient method for the introduction of samples into a high-speed gas chromatograph and is applicable to liquid–liquid extraction.\(^\text{(108)}\)
4.13.3.4 Headspace Autosamplers (Static Gas–Liquid Extraction) Headspace analyzers perform static gas–liquid extractions and are used to determine volatiles in liquids, solids, or complex matrices. Once the sample has been added, the vial is sealed with a septum cap, placed in a temperature-controlled environment, and allowed to equilibrate for a certain period of time. After the equilibrium has been achieved, a sample of the gaseous phase in the vial is removed by a gas-sampling syringe and injected into the gas chromatograph. Headspace autosamplers inject a portion of the gas that is in equilibrium with a sample into a thermostated sealed vial.\(^{109}\) Headspace analysis is used for the analysis of residual solvents, fragrances, and volatile pollutants in soil and water. Reproducible headspace analysis requires excellent control of all the parameters affecting the vapor pressure.

4.13.3.5 Purge-and-trap Automatic Samples (Dynamic Gas–Liquid Extraction) Purge-and-trap combines dynamic headspace trapping with thermal desorption. Volatile components are continuously purged out of a water sample (dynamic headspace), trapped on an adsorbent, and then desorbed quickly for introduction into the gas chromatograph (thermal desorption). Purge-and-trap is used mainly for analysis of environmental pollutants in water and for analysis of volatiles in beverages.

4.13.3.6 Thermal Desorbers Thermal desorbers are used in environmental sampling and are complementary to headspace analysis and analytical pyrolysis. Volatile sample components that are contained in a solid sample or have been absorbed on a solid adsorbent are thermally liberated in the sample in a stream of carrier gas and carried to the column. The advantages and disadvantages of sorbent sampling, active and passive techniques, solvent and thermal desorption, grab-sampling containers, cryogenic traps, and cold-trap concentration for the analysis of C\(_1\)–C\(_4\) hydrocarbons can be found in the literature.\(^{110}\) This technique is used for monitoring hazardous gases in the workplace and for environmental air analysis.

4.13.3.7 Pyrolyzers Pyrolyzers are used to thermally cleave non-volatile samples into volatile fragments, which are then analyzed by GC. Temperatures in the 500–1000°C range are normally used for the analysis of polymers, fibers, microorganisms, and geological samples.

4.13.3.8 Transfer Lines (Ambient Vapor Sampling Inlet Module) The ambient vapor sampling (AVS) inlet module,\(^{79}\) mentioned earlier, combines injection of gas with crude GC separation. Its main application is for field MS and for IMS measurements.

Figure 40(a) and (b) shows a schematic view of the Enviroprobe. The AVS is a valveless approach\(^{111}\) to injecting variable quantities of gases by modulating the time during which the carrier gas exchanges the carrier gas flow in tube two for the sample flow in the opposite direction. This approach permits resolution in milliseconds for the injection pulse width.\(^{72}\) The GC separation is performed in the transfer line between the injector and the detector. This approach minimizes the upstream dead volumes and at the same time reduces the sample adsorption sites.

4.13.3.9 Cryofocusing Trapping and Fast Desorption Cryofocusing of samples, followed by fast thermal desorption, at a rate of several thousand degrees Celsius per second, is an approach used to generate narrow injection pulses. One successful approach, originated at the University of Michigan,\(^{112}\) uses a cryofocusing capillary dimension trap for sample collection and capacitive discharge for heating the trap rapidly.\(^{113}\) This approach is now commercialized by Chromatofast (Ann Arbor, MI, USA) and is shown in Figure 41(a–c).

Figure 41(a) shows the sample collection and cryofocusing mode. In this mode, valve V\(_1\) is open, V\(_2\) is closed,

![Figure 40](image-url) Schematic view of the Enviroprobe (AVS) from FemtoScan. (a) In the injection mode, the two vacuum lines are opened and the sample gas is injected into the column. (b) By turning off the second vacuum line (middle connection), the inert carrier gas is forced through the column and creates a barrier between the supply of sample gas and the column. (Courtesy of FemtoScan Corp.)
and the cold trap is maintained at a low trapping temperature (between $-20$ and $-160^\circ$C, depending on the samples to be trapped). With the vacuum pump in the system, sample vapor is introduced and flows through the restrictors $R_2$ and $R_3$, then into the cold trap, where it is cryofocused. This reverse flow means the sample is introduced into the trap end closest to the separation column.

Figure 41(b) shows the backflush mode. Both valves are open, and flows through the column and the cold trap are from right to left. Therefore, any components that have not yet eluted from the column are backflushed toward the trap. If the trap is cooled to trapping temperatures, the backflushed components are cryofocused again for a subsequent injection.

Figure 41(c) shows the injection and separation mode. Valve $V_1$ is closed and $V_2$ is open, causing the flow through the cold trap to be from left to right. The trap is then rapidly heated with a capacitive discharge power supply. This serves to flash vaporize the sample and deliver it to the column as a narrow vapor plug. Injection bandwidths are around 5 ms.

This inlet system can interface to conventional split inlets for liquid samples or can be used to sample air directly or from containers such as Tedlar bags. For air sampling, an adjustable amount of preconcentration can be accomplished by adjusting sampling times. This injector feature also uses the reverse sampling facility. The sample is collected and reinjected from the same end of the trap, which helps minimize injection bandwidth, minimize degradation of thermally labile compounds, and limit sample contamination or carryover from the split inlet. In addition, this inlet design prevents the sample from coming into contact with the valves, preventing contamination and reactivity of the sample with valve inner surfaces.

Figure 42 shows an application of fast injection to the determination of solvents from paint. A total of 15 solvents were separated in $<1$ min on a DB-1 column. A conventional GC analysis for these compounds required a 1–2-h cycle time. This application analyzes the air in paint booths at automotive plants.

4.14 Gas Chromatography Detectors – Basic Terminology

Whatever detector is used, there are three major response characteristics of detectors: sensitivity, selectivity, and dynamic range. To be useful in a practical sense, stability and repeatability must also be considered.

4.14.1 Sensitivity

This is the response per amount of sample, i.e. the slope of the response–amount curve. The minimum amount on the curve is defined as the minimum detectable quantity (MDQ). The MDQ is practically defined as the amount of sample for which the peak height is twice the noise height (signal-to-noise ratio = 2).

4.14.2 Selectivity

Selectivity identifies which categories of compounds give a detector response. Some detectors, such as the TCD, sense almost everything and are considered universal. Others, such as the ECD, respond only to certain types of components and are useful when the detected component is present in a complex, nondetected matrix. Selectivity is usually expressed as the ratio of the injected quantities of two compounds that give the same output response. For instance, the selectivity of the ECD for anhydrides relative to hydrocarbons is 10 000 : 1.

4.14.3 Dynamic Range

Dynamic range is the range of sample concentrations over which a relative incremental change in sample concentration produces a similar relative change in the signal. This range can be quite large for certain detectors (seven orders of magnitude for the FID). For others, such as the flame photometric detector (FPD), it can be limited.

4.15 Gas Chromatography Detector Selection

The selection of the GC detector to be used is determined by the information desired. The compound structure is identified by a mass spectrometric detector (MSD) or an infrared detector (IRD). High sensitivity is achieved by the ECD, the nitrogen–phosphorus detector (NPD), and the MSD. High selectivity is provided by the ECD, NPD, FPD, and the MSD in the selected-ion monitoring (SIM) mode. The electrolytic conductivity detector (ELCD) and the PID also offer high selectivity for particular species. A general description of these detectors follows. GC detectors are covered in detail in the literature.\(^{65,67,115}\)

4.15.1 Flame Ionization Detector

The FID consists of an oxygen-rich hydrogen flame that burns organic molecules, producing ionized molecular fragments. The resulting ions are collected by a polarized collector (Figure 43). The FID is selective for materials that ionize in an air–hydrogen flame. Few ions are formed until an organic compound elutes into the flame. The resulting large increase in ions is collected by a polarized collector. The FID is characterized by a large dynamic range (\(10^7\)), high sensitivity (15 mC g\(^{-1}\)), low detection limit (10\(^{-12}\) g s\(^{-1}\)), and small dead volume (nanoliters). For these reasons, the FID is the most popular GC detector today. With optimized operating parameters and a good analytical column, it is possible to determine components in as little as 20 pg or about 5 ppb of sample gas.

The response of the FID depends on the flow rate of all three gases – carrier gas, hydrogen, and air – with hydrogen being the most critical. The flame is usually optimized by successive injections until the signal reaches its maximum.

4.15.2 Photoionization Detector

The PID consists of a UV lamp and an ionization chamber. The lamp is filled with a gas (usually argon or hydrogen) and produces emission lines characteristic of the gas when excited. The radiation passes through a metal fluorite window and into the ionization chamber or cell. There the sample absorbs the radiation and ionizes. Electrodes collect the ions; the current measured is proportional to the sample concentration (Figure 44).

Most of the energy is emitted at one frequency; the lamps are characterized according to the energy of this major emission line. The lamp is selected based on the ionization potential of the compound being measured and on the selectivity and sensitivity required. Lamps of 8.3, 9.5, 10.2, and 11.7 eV are available. Using a

![Figure 43 Schematic of an FID.](image-url)
10.2-eV lamp, the PID does not respond to C₁–C₄ hydrocarbons (ionization potential 10.5–12.98 eV) but does respond to C₅ hydrocarbons and above. Likewise, it does not respond to permanent gases (IP > 10.5 eV). It does respond, however, to aromatics, olefins, ketones, amines, etc. Thus for complex samples such as gasoline, PID chromatograms are much easier to interpret than those obtained with the FID.

The PID is a concentration detector with a dynamic range of 10⁷ and an MDQ of 2–3 pg benzene. Detector cell volume is an important specification for the capillary column. The available cell volume today is <30 µL, which may be acceptable for normal-speed capillary chromatography but not for high-speed variations.

4.15.3 Electron Capture Detector

The cavity of the ECD contains two electrodes with the effluents of the column passing between them. The cathode is coated with β-emitting radioactive material. The emitted high-energy electrons produce large amounts of positive ions and low-energy (thermal) electrons in the carrier gas. These electrons are normally collected by the positively charged electrode, thus producing a standing current of typically 10⁻⁹–10⁻⁹ A. However, when a material with an affinity for thermal electrons is present in the carrier gas, it captures some of these electrons, and consequently, the standing current that is observed is reduced. The essential elements of the ECD are summarized in Figure 45.

Instead of applying a steady direct current (DC) polarization voltage, a pulse of 1–3 µs at 50 V is applied to the electrodes every 150 µs. This pulse collects only free electrons, since the heavier negative ions cannot respond in this small interval and are swept out of detection by the carrier gas. The most common carrier gas selections for ECD are nitrogen and 5% methane in argon.

The ECD is highly selective. It responds to electrophilic species such as halogenated compounds. Pesticides give an excellent response with MDQs at the picogram level and over a dynamic range of 10⁴.

For successful ECD operation, it is important that the carrier and purge gases are clean and dry (99.9995%). Moisture, oxygen (leaks), or other contaminants must be avoided for stable operation of the detector. The column must be preconditioned before use. Finally, the use of a radioactive source is regulated by many governments and usually requires a license to be portable.

4.15.4 Nitrogen–Phosphorus Detector

The NPD (also called a thermoionic detector) uses a jet and collector similar in appearance to the FID. However, this detector is made selective for nitrogen- and phosphorus-containing compounds by a source of alkali metal salt positioned above the jet (Figure 46). This thermoionic source efficiently ionizes nitrogen- and phosphorus-containing organic molecules. Ions are collected, and the resulting current is measured for the chromatogram.
The NPD has proven valuable in pesticide analysis, where its selectivity replaces costly extraction or concentration steps. It can detect a few picograms of nitrogen- and phosphorus-containing organic compounds. The NPD has a dynamic range of $10^4$ and has a selectivity of 10,000:1 to 100,000:1 by weight of nitrogen and phosphorus to weight of carbon. It does not detect inorganic nitrogen, such as N$_2$ and ammonia.

4.15.5 Flame Photometric Detector

An FPD is essentially a flame emission spectrometer with its design optimized as a GC detector. This is an element-specific detector that responds to a particular molecular species. It is used primarily for the determination of sulfur- or phosphorus-containing compounds.

The sample contained in the column is fed to a flame, where the individual atoms are excited to higher electronic states by the energy of the flame. These excited atoms and molecular fragments subsequently return to the ground state with the emission of characteristic atomic or molecular band spectra. In the case of sulfur, the band emission from the S$_2$ species at 394 nm is used, while the 526-nm emission is used for phosphorus.

A narrow band-pass filter is used to isolate the appropriate analytical wavelength, and its intensity is measured by a photomultiplier (Figure 47). The FPD response to sulfur and phosphorus is a factor of $10^4$ greater than its response to hydrocarbons, and the MDQ is at the subnanogram level. The response to sulfur concentrations is not linear. It should be proportional to the square of the sulfur concentration; in practice, a factor of 1.8 provides a better fit to the calibration curve.

Figure 48(a) and (b) illustrates the selectivity that results when the FPD is used with capillary columns for the analysis of sulfur compounds in petroleum naphtha. Interference from the concentrated hydrocarbon background is not observed.

One potentially serious problem with the FPD is the undesired light absorption that can occur in the flame. This can happen by hydrocarbon quenching from collision when a high concentration of carbon dioxide occurs in the flame at the same time as the sulfur atom species. Also, self-quenching can occur at high concentrations of the heteroatom species. In this case, collisional energy absorption or reabsorption of the photon by an inactivated species could effectively prevent the photon from reaching the photomultiplier.

The flame conditions are critical to successful operation. Gas flows are also critical to optimizing selectivity and sensitivity. Temperature can also have a significant effect on sensitivity. Finally, condensation of water, especially with halogenated solvents or samples, will cause corrosion in the detection zone or fogging of the window leading to the photomultiplier.

In summary, the FPD has a number of limitations. These include its response dependence on the O$_2$ : H$_2$ ratio, the H$_2$ flow rate, the type of sulfur compound, and even the length of time the flame has been burning. In addition, the best results are obtained by generating a calibration curve for each compound in the mixture.

4.15.6 Thermal Conductivity Detector

The TCD responds to any compounds with a thermal conductivity that is different from that of the carrier gas. Hydrogen and helium are recommended carrier gases because of their exceptionally high thermal conductivity differences from all compounds. The principle of
Figure 48 Sulfur compounds in the complex hydrocarbon mixture of petroleum naphtha using (a) FID and (b) FPD.  
(Courtesy of Agilent Technologies.)

operation of a TCD is fairly simple: when the analyte is present in the carrier gas, the thermal conductivity drops and less heat is lost to the cavity wall. Under constant-temperature operation the voltage supply to the filament drops. This change is recorded and measured.

In practice, the TCD is extremely temperature sensitive. One can show that a difference of $10^{-6}^\circ\text{C}$ is detectable in a single-filament detector; for this reason, a TCD is usually composed of two identical cells physically closed from each other and part of a Wheatstone bridge. One of the cells sees only pure carrier gas and the other is connected at the output of the column (Figure 49). Although this procedure reduces the variations in signal caused by changes in block temperature and any other common mode signal, such as variations in carrier gas flow rate, it does not eliminate their effect on the final signal. Careful thermal design is of critical importance.

An alternative solution to the stability problem has been offered. It has been shown that it is possible to produce a stable and fairly rapidly responding TCD by using only one thermal conductivity filament and alternately switching (at 10 Hz) the column and reference flow of carrier gas and effluents from the column (Figure 50). This pneumatic modulation has the advantage of almost completely eliminating the common mode signal and producing a signal with much lower
baseline noise, drift, and wander. Assuming that a minimum of 10–20 data samples are required to define a peak accurately, pneumatic modulation restricts the minimum peak width to approximately 1 s and is not suited for fast chromatography unless makeup gas is used.

The dynamic range of the TCD is $>10^4$ and its detection limit is $<1$ ppm. Samples that react with the filament can reduce the TCD’s sensitivity and create instability in the baseline. Nonmodulated designs are particularly sensitive to common mode signals such as flow and temperature variations, and require long stabilization times. Generally, it is difficult to operate a nonmodulated design for high-sensitivity field operations. The pulse-modulated single-filament TCD showing the inertness and dynamic range of the detector is shown in Figure 51.

4.15.7 Electrolytic Conductivity Detector

The ELCD can be used to detect halogen-, sulfur-, or nitrogen-containing compounds selectively. This is done by mixing the effluents with a reaction gas (oxidizing or reducing, depending on the analysis) in a reaction tube (usually nickel). The resulting products are then mixed with ionizing solvents, producing a conductive solution (Figure 52). This conductivity is measured and recorded.

In the case of halogen analysis, the column effluent is reduced with $\text{H}_2$ at 850°C in a nickel reaction tube, producing strong acids (e.g., hydrogen chloride from chlorinated components). This gaseous product is then dissolved in $n$-propanol, and the change in solvent conductivity is measured. Other reduction products besides the hydrogen halides do not ionize and, therefore, do not cause an increase in conductivity in the slightly acidic $n$-propanol solvent.

The sensitivity for chlorinated compounds is $<1$ pg and the dynamic range is $1 \times 10^6$. For sulfur, the sensitivity is 2 pg and the dynamic range is $1 \times 10^4$. For nitrogen, the sensitivity is 4 pg and the dynamic range is $1 \times 10^4$. Selectivity is $100 000:1$ by weight of halogen relative to carbon and $10 000:1$–$100 000:1$ for sulfur and nitrogen, depending on the compound and element.
FIELD-PORTABLE INSTRUMENTATION

Higher reactor temperatures (950 °C) are necessary for compounds that are more difficult to reduce, such as PCBs. Using different solvents and gases, the ELCD has been made to detect heteroatoms other than halogens. Good results have been reported for sulfur and nitrogen selectivity.

4.15.8 Summary

Figure 53 shows how common detectors compare with respect to sensitivity and dynamic range. An MDQ below the nanogram level (in parts per million) can routinely be detected. An MDQ at the picogram level (in parts per trillion) is at the limit of detectability of most detectors operating without preconcentration. The dynamic range of GC detectors is in excess of 4–5 decades.

Table 9 summarizes the main characteristics of GC detectors in terms of MDQ, dynamic range, and selectivity. All these detectors can be adapted to field operations but some of them will require more attention than others when used to maximum sensitivity. The main difficulties for the user are the time it takes to stabilize the detector and its susceptibility to environmental parameter variations, such as ambient temperature.

Other detectors such as mass spectrometers and ion mobility spectrometers are used for field operation and will be discussed below. The AED has field applications for which unequivocal analytical information is needed. It has been successfully tested in various quantitative applications, such as the evaluation of lead, sulfur, and oxygenates in gasoline. The AED has also been used to identify base neutral pollutants, herbicides and PCBs. It has also been used successfully in unfriendly territory for treaty verification.

The appropriate detector is determined by the class of compounds to be analyzed. Some of the applications of the various detectors are summarized in Table 10.

The FID and the PID have long been used in hand-portable units, and their ruggedness has been demonstrated under difficult conditions. The NPD is similar in design to the FID; it can be operated easily and provides valuable information.

The TCD, at least in the flow modulation mode of operation (one filament), can also provide reliable data and can stabilize in a matter of minutes. When operated in a differential mode at the maximum sensitivity, the dual-filament TCD detector has a tendency to drift endlessly. Since in this mode the TCD relies on the equality of resistance between the reference and detection filaments, it is also susceptible to aging and becomes more sensitive to common mode signal variation after the resistance of one filament changes irreversibly. This may happen when the detection cells see a corrosive sample. Again, the single-filament TCD is insensitive to common mode signal variations.

The ECD has many potential field applications but may not be practical, since it can be easily contaminated; for this reason it requires a lot of attention when operating in the low range of detectability and may not be practical. The FPD is difficult to operate quantitatively in the field.

because it requires a calibration for each compound; also, the sensitivity of the FPD varies with the time the flame has been lit. Finally, the ELCD has some potential applications for field measurements but is bulky and not designed for field operation.

4.16 Portable and Transportable Gas Chromatographs

This section gives general information about field gas chromatographs and describes some of the instruments available in 1996. The intent is not to promote or criticize the models selected but to provide the reader with a tool for selecting an instrument by understanding the pros and cons of each.

The market for portable gas chromatographs is growing steadily, and manufacturers are developing innovative ways to reduce the size and weight of GC instruments. Each new design represents a trade-off between functionality and portability.

High boiling-temperature compounds require the GC column to operate above ambient temperature and, therefore, necessitate larger amounts of electrical power than can be realistically supplied by batteries. The most common trade-off for portability is to provide analysis of only VOCs and to run the column and the detector just above ambient temperature. This approach allows the instrument to be operated from battery packs for several hours.

Portable instruments usually eliminate interactive interfaces, such as keyboards and displays, and provide only computer interfaces to reduce weight and size. However, this compromise places the burden on the user to provide a computer device or network.

One method of reducing the chromatograph to its simplest functionality is to limit its analytical capabilities. The column used is a narrow-bore column of length >1 m, which is long enough to give a crude separation but no baseline separation of complex mixtures. The column is heated to several hundred degrees in a crude oven and has enough separation ability to serve as the front end of a mass spectrometer or an ion mobility spectrometer for which the peaks can be identified without baseline separation.⁷³,₁₁₉–₁₂¹ In this type of trade-off, the burden of analytical separation shifts from

the gas chromatograph column to the sophisticated detector and data interpretation.

4.16.1 PE Photovac

PE Photovac has two notable portable instruments: the SnapShot GC, which has a low weight 4.5 kg (<10 lb), and the Voyager, which is a combined gas chromatograph and total VOC analyzer with built-in computation and data-logging capabilities. The Voyager is also low in weight, 6.8 kg (15 lb). The main features of these two instruments are summarized in Table 11. The column used in both of these instruments operates isothermally at <100 °C and is, therefore, used primarily for VOCs. Raw data are stored during analysis and are available later for data reduction. Each of these instruments can be connected to a network for either remote control or data retrieval. Both have a small canister for the supply of carrier gas and a battery pack that allows typically 4–9 h of field operation; both have internal sampling pumps for automatic headspace analysis of water or soil.

An exploded view of the SnapShot instrument is shown in Figure 54. This instrument is application-driven and operates with interchangeable modules.

Factory-programmed application modules include Compound Library, Analyzer Set-Up, and Analytical Method Software for Automatic Compound Identification and Measurement.

The Voyager portable GC is shown in Figure 55. This instrument has a number of unique features, including a built-in three-column set for analysis of VOCs with a wide range of boiling points and molecular weights. A dual PID–ECD system allows the determination of both chloroalkane and chloroalkene solvents of importance in environmental monitoring. Inorganic gases such as hydrogen sulfide, carbon disulfide, nitric oxide, arsine, and phosphine can also be detected. Confirmation analysis can also be performed by injection of the sample on each of the three columns, each of a different polarity. The Voyager GC, like the SnapShot GC, has Intrinsic Safety Classification, which makes it useful for hazardous confined-space entries to refineries and chemical plants.

4.16.2 MTI Analytical Instruments

MTI Analytical Instruments (Fremont, CA, USA) uses silicon wafer fabrication technology to micromachine
MTI Analytical Instruments combines the varied aspects of silicon micromachining technologies to fabricate a gas injector and a TCD (Figure 56). The gas injector is a hybrid combination of micromachining technology and conventional machining. The small physical dimensions of the valves and restrictor channels result in the sample reaching the column as a sharp plug.

The small internal volume of these micromachined parts has allowed MTI to design a portable gas chromatograph that has little extra column dead volumes. The instruments can, therefore, use short, narrow-bore capillary columns and perform a typical gas analysis in 20–30 s, whereas several minutes are needed for conventional gas chromatographs (Figure 57).

Table 12 lists some of the features of the low- and high-temperature versions of the P200. Each version has battery packs and gas supplies that make field operation possible for several hours (depending, of course, on the amount of power drawn from the battery pack). The instruments accept gaseous samples only and can operate in isothermal conditions. The two modules differ in stationary phase (column material), operating temperature of the column, and injected volume. The sample transfer line and the injector operate at lower temperatures than the column and the detector. This design may create cold spots and condense some high boiling-temperature compounds. Therefore, it should be considered primarily for VOCs. It cannot be used for the injection of a liquid sample, but vapors with high boiling points up to 220 °C can be analyzed.

Figure 58 shows an inside view of the P200 Micro GC. The sample inlet, at the front of the instrument, is heated to 110 °C to prevent water condensation. A gaseous sample is pumped into the instrument with a built-in pump and analyzed in up to four GC modules simultaneously. A rechargeable carrier gas tank provides up to 40 h of operation. The rechargeable battery pack can operate a maximum of 8 h before needing to be recharged.

4.16.3 Model 311D from HNU Systems Inc.

HNU offers a full VOC/SVOC gas chromatograph for operation in the field or in a laboratory. This instrument includes a column oven with multiramp temperature programming or isothermal operation at up to 200 °C, heated syringe injector and detectors (one or two), sample pump with automatic gas sample valve, or a Tenax® sample concentrator/injector. Detector options include PID, far-UV, ECD, TCD, FPD, and FID. Detectors can be configured singularly or in series, with single or multiple columns in the oven. The gas chromatograph includes a built-in carrier gas supply and requires an external AC to operate. The features of the 311D...

are given in Table 13, and the instrument is shown in Figure 59. In the figure, the gas chromatograph is controlled from an external PC. The carrier gas supply is in the detachable instrument cover. The heated injector is used for syringe injections of liquids or gases. Built into the GC is a sample pump and either a gas sample valve or Tenax® gas sample concentrator/injector for single or continuous analysis. The concentrator improves the lower detection levels for most compounds.

The performance of this gas chromatograph has not been degraded for portability; the performance of the 311D in the field is similar to that of a laboratory gas chromatograph. One way to check the performance of an instrument is periodically to inject a test mixture and compare the resulting chromatogram with a standard. The measured retention times and relative peak heights should not vary from the standard by more than some agreed-on value. For example, according to HNU Systems, the repeatability of retention times (which is a measure of temperature and flow stability) is better than 0.5%.

4.16.4 Agilent Technologies 6890 Gas Chromatography

Mobile laboratories are equipped with conventional nonportable instruments or combinations of instruments, such as GC/MS. Field applications requiring versatile, high-quality chromatographic data rely on laboratory instruments operating from mobile shelters. The 6890 GC from Agilent Technologies (Palo Alto, CA, USA) is one such instrument used in the field.

The 6890 GC is at the extreme end of the spectrum of field instruments (Figure 60). It is not hand-portable, and requires a bench and several kilowatts of electrical power. This instrument is not designed to operate in extreme temperature and dust conditions; thus one could easily question its choice for field applications. However, it is versatile, given the range of detectors and the nature of samples it can analyze. The specifications for this model are shown in Table 14. A major advantage of the 6890 GC is that it operates with specific detectors, including MSD and AED, and thus provides positive identifications...
that cannot be achieved with conventional GC detectors for gas, liquid, and solid samples. Since this instrument must operate inside a shelter, it can be connected to sophisticated data reduction and communication tools, providing an integrated solution to high-quality analysis.

4.16.5 General Comments

GC is a simple technology that is inexpensive and powerful. This technique has been used for several decades and still has an attractive future. The development of portable gas chromatographs is relatively recent and shows that the field is growing, although the performance limitations of these instruments still require the field operation of conventional instruments. Portable gas chromatographs available today do not yet offer the same versatility as laboratory instruments. However, by operating directly at the site, they can give valuable on-the-spot qualitative analytical information.

The major advantage of portable gas chromatographs lies in their ability to make measurements directly in the field, thus eliminating the transport and manipulation of samples. If used properly, they can provide limited but immediate information about the nature and concentration of compounds. The more specialized portable instruments provide unskilled users with tools adapted to their applications. The Photovac SnapShot offers modules for specific applications and is a good example of a clever compromise between portability and versatility.

“Just enough GC” is an interesting approach applied to the design of portable instruments. This concept, combined with the wireless networking of analytical instruments in the field, opens the market for totally new types of portable instruments. The portable gas chromatograph is a sensor under interrogation by a remote unit.

Portable instruments are limited by the range of samples that they can handle. For instance, it is not possible today to analyze semivolatile compounds with a portable unit operating on batteries, since the amount of power necessary to heat the oven and the column cannot be supplied by battery packs. Only alternative thermal designs to the conventional heating of the column by a convection oven may provide a solution to this limitation.

The GC hardware is also a limiting factor. When conventional GC hardware is used with portable instruments it increases the power demand and size of the instrument to unacceptable levels. Most of the injectors and detectors (with only a few exceptions, such as the microthermal conductivity hardware developed by MTI Analytical Instruments) have been designed for laboratory instruments. By microfabricating its detector with technologies borrowed from the semiconductor industry, Agilent Technologies has demonstrated that small-volume detectors can be developed that are well adapted to small-bore columns. The result is faster analysis of field samples.

The major challenge faced by the manufacturer of field gas chromatographs is to determine the maximum range of compounds that can be analyzed by a given instrument. HNU, with the Model 311D, can operate at up to 200 °C and accepts a broad range of columns, including packed columns. HNU also offers a range of specific detectors for analysis of gases, hydrocarbons, and halogen compounds. The result is versatile instruments that can analyze PCBs, perform static headspace analysis, or monitor landfill gas. The price to pay for this versatility includes their larger size and weight and the fact that they need greater electrical power.

At the upper end of price and size, the 6890 GC from Agilent Technologies is by far the least portable and field-operable instrument, but it offers several valuable advantages when high-quality data are needed. Since this instrument must operate in a mobile laboratory, it can operate with a broad range of nonconventional detectors such as MSDs and AEDs. The analytical tools provided give the user the capability to get the same quality and versatility of measurement for gas, liquid, and solid samples as in the laboratory. Although the instrument operates in the field, there is still a need to transport samples to the mobile laboratory, which can be remote from the measurement site with the risk of sample degradation that this implies.

5 MASS DISPERSION METHODS FOR ENVIRONMENTAL MEASUREMENTS

Two popular techniques illustrate analysis based on analyte mass or ion size: MS and IMS.

The former method is widely accepted by government agencies such as the USEPA. It is applicable to most of the compounds found in air, soil, and water at a detection level of a few parts per billion; differentiation of molecules is based on their mass. IMS uses ion size to differentiate between analytes. This is a truly hand-portable technique in which the chemistry has been adapted to a specific application. Both techniques are used with GC to effect a separation before analysis.

5.1 Mass Spectrometry

MS is a microanalytical technique that requires only a few nanomoles of sample to obtain characteristic information regarding the structure and molecular weight of the analyte. It is a destructive technique in which the sample is consumed during analysis. In all cases, some form of energy is transferred to the analyte molecules to effect ionization. In most cases the nascent molecular ions of the analyte “explode” in a predictable fashion into a variety of fragment ions; the resulting fragmentation pattern constitutes the mass spectrum. In principle, the mass spectrum of each compound is unique and can be used as a chemical “fingerprint” to characterize the sample.

Figure 61 gives a synopsis of the entire process of analysis by MS, culminating in the bar graph mass spectrum often published in the literature. For analysis by a conventional mass spectrometer, the sample must have a vapor pressure of >1.3 N m⁻² (>10⁻² mmHg), because molecules of the sample migrate by diffusion from the inlet system into the ionization chamber. The inlet may be either a direct probe or a GC inlet. As the neutral molecules randomly diffuse throughout the ion source to the ionization chamber,

---

Figure 61 Synopsis of analysis by MS. This example illustrates the fragmentation of the original vapor sample into fragment ions. M, molecules of the sample in the vapor state.
only a few hundredths of a percent of them are ionized. This fraction is referred to as the ionization efficiency.

The most common ionization process, electron ionization (EI), is achieved by bombarding the sample with electrons at 70 eV energy. The ionization process in general is nothing more than the transfer of energy to the neutral molecule in the vapor stage, giving the neutral molecule sufficient energy to eject one of its own electrons and, therefore, become charged with a residual positive charge. This process produces a molecular ion with a positive charge (Figure 61). This molecular ion still has considerable energy, and much of that energy can be dissipated by fragmentation of its chemical bonds.

This decomposition of various chemical bonds leads to the production of fragment ions whose mass is equal to the sum of the atomic masses of the group of atoms retaining the positive charge during the decomposition process. It is important to realize that not all of the molecular ions decompose into fragment ions. Molecules producing a molecular ion that is stable tend to survive or not to fragment, and an intense molecular-ion peak is recorded. During the analysis of a compound having a molecular ion that is unstable, nearly all of the molecular ions decompose into fragment ions, and in these cases the mass spectrum contains only a small peak for the molecular ion.

The task now is to analyze all the ions created in the ionization chamber according to mass. Ions have an electrical charge that permits them to be focused by various ion optics potentials to form a well-collimated ion beam. This beam of ions is accelerated out of the ionization chamber and into a mass analyzer.

### 5.2 Mass Analyzers

The mass analyzer can be any one of several types: quadrupole (which includes quadrupole filter and ion trap), Fourier transform mass spectrometry (FTMS), ion cyclotron resonance (ICR), time-of-flight (TOF), and magnetic sector. Regardless of which is used, the result is the same. The ions are analyzed according to the sum of the atomic masses of the group of atoms retaining the positive charge along a mass scale. During the process of data recording and reduction, the data can be arranged in tabular form or in bar graph format. Additional details concerning the design and operating principles of mass spectrometers in general can be found in the literature.\(^{(127-129)}\)

#### 5.2.1 Time-of-Flight

In TOF mass spectrometers, ions are given a kinetic energy with a high-voltage pulse. Another important parameter is the duty cycle of the instrument, defined as the ratio of the time when the TOF is operating to the period between pulses. For instance, in orthogonal acceleration TOF, the duty cycle is the ratio of fill time of the sample in the deflector to the period of the repetition pulses. The duty cycle is a measure of the efficiency of measurement of the instrument. The higher the duty cycle number, the more efficient is the TOF.

Ions then drift through a tube to a detector (Figure 62). The length of the tube (between a fraction of a meter and several meters) determines the resolution of the TOF. The longer the drift tube, the better is the resolution. Although all ions leave the source together, ions with smaller mass-to-charge ratios accelerate to a higher velocity than heavy ions of the same charge and will reach the detector first. Identification is done by measuring the transit time of the ion. Since the typical drift time for the largest ions is \(<50\mu s\), the accelerating pulse could be repeated at approximately 20 kHz.

In a TOF system, a burst of ions (with a distribution of masses) that is accelerated to a constant energy will eventually be resolved in space (ions of similar mass will be grouped together), because each ion is travelling at a different velocity. The \(w = zeV = (1/2)mv^2\) equation predicts an inverse quadratic relationship between \(v\) and \(m/z\).

In this instrument, some ions reach the detector at different times, and the \(m/z\) value of an ion is determined by its time of arrival at the detector. Ions of low mass reach the detector before those of high mass. Voltages within the system, except for the “pulser”, are constant (typically from a few hundred volts to 1000 V DC). This contrasts with the other mass filter types, in which nonselected ions are filtered out by changing magnetic or electric fields.

There are two principal modes of operation in time-of-flight mass spectrometry (TOFMS): pulsed operation and continuous operation. In the continuous mode, ions are produced nearly all the time, thereby increasing the sensitivity of the TOF by at least one order of magnitude. The ionization process takes place for at least 70% of the TOF cycle (typically 100 \(\mu s\) for a mass range of 1000 Da) and is shut off only during the period of ion acceleration (typically a few microseconds). In the pulsed mode, the cycle is initiated by ionizing the molecules for typically 1 \(\mu s\) and then by pulsing the ions into the acceleration region for 1–2 \(\mu s\), where mass separation is effected. The larger bundle of ions formed in the continuous mode

---

Figure 62 Basic description of a TOF mass spectrometer, showing the main components of the analyzer. (Courtesy of Agilent Technologies.)
leads to increased sensitivity but decreased resolution compared to the pulsed mode of operation.

TOFMS requires a data acquisition system capable of digitizing at a rate of about 100 MHz to maintain a timing resolution of 10 ns in the instrument. The data must be processed further at similar rates. Although TOFMS is well suited to acquiring full spectra, it is also well suited for SIM by integrating the ion current at each given m/z value for several TOF cycles.

Manufacturers are highly motivated to reduce the size of drift tubes to make their products more portable. With the use of V-shaped and linear reflectors, which are well suited for field operations, Kore Technology (Cambridge, UK) has been able to reduce the length of its Model T-CAT drift tube to 0.2 m.\(^{(130)}\)

### 5.2.2 Quadrupole Filter

The quadrupole mass filter consists of four conductive rods that are used to shape an electrodynamic field. This nonmagnetic mass spectrometer employs a combination of DC and radiofrequency (RF) potential as a mass filter. Ideally, the four rods arranged symmetrically (Figure 63) should have the shape of a hyperbola in cross-section.\(^{(131,132)}\) This can be accomplished, as in the case of the Hewlett-Packard Model HP5973A MSD, by using a single piece of 20-cm long quartz, with a portion of the inner surface made conductive. The magnitude of the field determines which ion will pass through the quadrupole to the detector.

The entire mass spectrum is scanned as voltages are swept from a pre-established minimum to a maximum value (approximately 400 V DC and 2000 V RF), but at a constant DC: RF ratio. This ratio defines the operating stability, sensitivity, and resolution of the instrument.\(^{(127)}\)

The quadrupole features reasonable sensitivity (picogram range) and scanning rate (several thousand daltons per second), which are adequate for use with small-bore GC columns that produce peaks in the hundreds of milliseconds range. Another advantage of the quadrupole is that it produces mass spectra with a constant mass resolution, i.e. the separation of the peaks at \(m/z\) 400 and 401 is the same as for \(m/z\) 30 and 31.

A quadrupole can be operated in one of two modes: scanning or SIM. In the scanning mode, voltages are swept from a pre-established minimum to a maximum value at a constant DC: RF ratio, therefore scanning the sample over the overall mass range of the analyzer. In the SIM mode, the DC: RF ratio is set constant to a value that sets a measurement to a predetermined \(m/z\) ratio. In the SIM mode, the analyzer acts as a narrow-band filter and rejects all the other masses. To summarize, the scanning mode leads to more versatility (no knowledge about the exact masses to be monitored is required) but less sensitivity than the SIM mode.

The quadrupole mass spectrometer is more capable of maintaining quality output at higher pressures than other types of mass spectrometers; this may be an advantage in GC/MS where a constant flow of carrier gas is supplied to the analyzer. The only harmful effect of higher pressures (\(10^{-4}\) Torr) is that once the mean free path is less than the tube length, molecular collisions result in loss of ions to the poles and thus loss of sensitivity linearly proportional to the increase in pressure.

The quadrupole is well suited for SIM because selected ions from any region of the mass spectrum can be monitored without altering the optimum conditions in the ion source or mass analyzer. Furthermore, the parameters (superimposed RF and DC fields) that control the mass scale can be changed rapidly with good response and are well stabilized through the mass range. These features are particularly desirable for computer-controlled operation of the MS for ion monitoring.

Quadrupole MS systems produce EI spectra that can be compared with accepted classical library spectra for positive identification of either target compounds or unknowns. A major advantage of this feature is the predictability of data. Even if the spectrum of an unknown is not in a library, the spectrum can be interpreted by using isotope ratio calculations and well-established fragmentation patterns.

One limitation is that the sweep time cannot be reasonably reduced to below 10 ms, thereby limiting the rate of acquisition of chromatographic signals to a peak width of approximately 100 ms. When the ratio of peak width to sweep time is too small (i.e. 10:1), the spectra can be distorted by the slope of the GC peak, for

![Figure 63](image-url)
which heavier masses are augmented relative to lighter ones on the GC peak’s upslope, and diminished on the downslope.

5.2.3 Ion Trap

In the ion trap, ionization and mass filtering occur in the same place.\textsuperscript{(127)} A conceptual schematic of the ion trap detector (ITD) is shown in Figure 64.\textsuperscript{(133)} The top end cap, a ring electrode, and bottom end cap are electrically insulated from one another. Sample molecules enter the central cavity of the ion trap from the inlet. A filament produces a beam of electrons that penetrates into the cavity and interacts with the molecules in the cavity. An electrical field is generated by an AC voltage applied to the ring electrode. This electrode is between caps on each end of the cavity. Ions of selected mass-to-charge ratios are trapped within the electrical field. Ions over a specified range of $m/z$ values are trapped by appropriately selected RF and DC voltages.\textsuperscript{(134)}

A mass spectrum is produced by ramping the electrical field, which ejects ions from the cavity according to their mass-to-charge ratio, thus producing a mass spectrum. The ion trap is scanned from low to high mass by increasing the voltage on the ring electrode.

The ion trap has some advantages over most other forms of mass spectrometer in terms of size, weight, and pumping requirements. These advantages make the ion trap attractive for field applications.

Under favorable conditions, almost 100% of the parent ions can be converted to product ions, although a 10–50% conversion is more typical. The analogous conversion in most beam-type MS experiments is one to three orders of magnitude lower, implying significant reductions in detection limits.

Figure 64 Exploded view of an ion trap. (Courtesy of Agilent Technologies.)

The major drawbacks of the ion trap as a mass analyzer arise from the much greater ion densities that can be encountered in an ion trap instrument relative to those encountered in ion beams in most analytical mass spectrometers. High densities of ions of like charge can adversely affect the ion trap experiment in several ways, such as imposing a limit on the number of ions that can be stored, thereby limiting considerably the dynamic range.

5.2.4 Ion Cyclotron Resonance Mass Spectrometer

Although a product based on ICR technology is not yet available, the technology is attractive and therefore will be discussed. One prototype of such an analyzer was developed by Lawrence Livermore National Laboratory (LLNL) (Livermore, CA, USA).

ICR is the operating principle of the Penning ion trap. Ions are created inside the trap, and analysis and detection are also done there. Both features reduce ion loss and allow the ions to be sampled many times. A traditional Penning ion trap is a rectangular box that sits inside a powerful electromagnet (Figure 65a). A gas is introduced into the box and ionized by an electron beam. Two opposing ends of the box receive a positive electrical charge; the four sides, forming a square tube along the magnetic field direction, receive a less positive charge. The positively charged ions are repelled by the positively charged ends, thus the electrical voltage prevents the ions from leaving the box along the direction of the magnetic field. If the positive ions try to leave the box across the direction of the magnetic field, i.e. toward any of the less positive sides, they are deflected by the magnetic field into cyclical orbits, called cyclotron motion.

The frequency of this cyclical motion is determined by the magnetic field and the ratio of the ions’ electrical charge to their mass. Because the values of the magnetic field and the ions’ electrical charge are known, the mass of a trapped ion can be determined from the frequency of its orbit. This method of determining an ion’s molecular weight and thus its identity is known as ion cyclotron resonance.

Fourier transform algorithms have been applied to this technique, thereby improving its performance. For FTMS, the ICR instrument is operated in a pulsed mode. In Figure 65(a), a burst of electrons forms an assortment of ions in the cell. In the presence of a constant and uniform magnetic field (Figure 65b), all ions move in circular orbits with a characteristic cyclotron frequency $w_c$, which depends only on the ions’ $m/z$ value (Equation 21):

$$w_c = \frac{zeB}{2\pi m}$$

(21)

In Figure 65(b) a frequency-swept chirp signal is applied to the cell. Ions that experience oscillating fields equal
in frequency to their cyclotron frequency absorb energy from the circuit generating the chirps. During this process, these ions move to orbits of larger radii and become in phase with the exciting field. In Figure 65(c) the translationally excited ions move coherently between the receiver plates and establish an image current in the external conducting network attached to these plates. Because the chirp contains all the excitation frequencies, the ions transmit a complex RF signal that contains the frequency components characteristic of all of the ions present. The resulting total time-dependent image current is subjected to Fourier transformation, which resolves these components and produces a database for the mass spectrum. For low-resolution GC/MS, the pressure requirements are comparable to those of other common MS types, but to reach levels of performance identical to quadrupole or ion trap, high vacuums are likely to be needed.

FTMS is unique in that increased measurement times increase both sensitivity and resolution. This advantage derives from the fact that in FTMS the ions are not consumed during the detection process. Furthermore, all the ions at all masses are detected simultaneously in a process that could be viewed as frequency-array detection. The FTMS procedure provides an integrating effect that optimizes the signal-to-noise ratio and minimizes the problems due to a changing partial pressure of the analyte in the ion source, as in GC/MS applications.

At the present time there are not enough data to conclude that this technique is going to be a potential competitor for field applications. LLNL developed an award-winning prototype of an FTMS instrument based on ICR. The prototype of weight < 12.3 kg (33 lb) uses a battery, fits into a small attaché case, and has an accuracy of 1 × 10⁻³. The permanent magnet is designed to optimize the magnetic field. It is cylindrical, 7.6 cm (3 in) across and 5.7 cm (2.3 in) high, with a center bore of slightly less than 2.5 cm (1 in). A thin-walled vacuum chamber containing the ion trap fits inside the hole. A small ion pump, along with a miniature cryogenic pump, maintains the tube’s vacuum pressure. A miniature piezoelectric inlet valve admits gas to be sampled into the tube. There is also a pulse electron beam that ionizes the gas in the trap. This unit is claimed to have a mass range of 3–1000 Da and a detection limit of 20–100 atoms, but it requires a high vacuum, in the region of 10⁻⁸ Torr, to operate with this kind of sensitivity, making it less attractive for a portable instrument coupled with a gas chromatograph.

5.2.5 Magnetic Sector

The magnetic sector mass spectrometer uses a magnetic field to separate ions (Figure 66). Sample ions are accelerated out of the ion source and through a magnetic
field. The mass analyzer of this type of instrument is a sector-shaped magnetic field that disperses the total ion beam from the ion source into discrete ion beams of individual $m/z$ values through a process of momentum dispersion and direction focusing.

The $m/z$ of any ion traversing a fixed radius (fixed magnet geometry) can be related to the magnetic field and accelerating potential by Equation (22):

$$
\frac{m}{ze} = r^2 \frac{B^2}{2V} \tag{22}
$$

It is common practice not to deal with the absolute charge on the electron, and for convenience it is assumed to be unity. Thus Equation (22) is often found in the simplified form shown in Equation (23):

$$
\frac{m}{z} = r^2 \frac{B^2}{2V} \tag{23}
$$

The radius of curvature of an ion trajectory is proportional to its momentum ($mv$). Therefore, the total ion beam is dispersed into many individual ion beams, each having its characteristic radius of curvature in the region of the magnetic field. The imposed accelerating potential $V$ and magnetic field $B$ permit those ions of a specific mass $m_1$ to follow a trajectory to the detector, whereas the heavier ions of mass $m_2$ ($m_2 > m_1$) follow a trajectory that leads to collisions with the walls of the analyzer. Because the instrument has a fixed radius of curvature, either the magnetic field or the accelerating potential must be scanned to collect the mass spectrum.

Magnetic scanning is advantageous in that the entire mass range may be scanned while the instrument maintains optimum accelerating potential. A minor disadvantage is related to the quadratic dependence of $m/z$ on the value of magnetic field $B$. As the mass spectrum is scanned, the peaks at the high mass end appear closer together than do those at the low-mass end.

The combination of magnetic field and the forward velocity of the ions exerts a lateral force on the ion, causing it to follow a curved path. The radius of the curve depends on the $m/z$ ratio of the ion, the strength of the magnetic field, and the charge and velocity of the ion (the last two values depend on ion source behavior). For a given strength, only a single $m/z$ ion will curve at the radius needed to reach the detector opening. All others will miss and be pumped away by the vacuum system.

Advances in GC continue to impose demands for faster scan rates on the mass spectrometer in GC/MS applications. The scan rate of a magnetic instrument is limited by the reluctance of the electromagnet. Laminated magnets permit more rapid changes in the magnetic field so that the mass range can be scanned at rates approaching 0.1 s per decade. Two major disadvantages of magnetic MS for field applications are the weight associated with the magnet and the potential effect of the magnetic field surrounding the instrument. If scan speeds exceed a certain rate, the magnetic field can change significantly during the ion transit period (the time required for an ion to traverse the magnet), causing ions to follow a distorted path to the detector. This results in losses in both resolution and sensitivity.

5.2.6 Cycloidal Mass Spectrometry

Cycloidal (trochoidal) MS is another emerging technology that has applications with residual gas analyzers. This technique could also potentially be used as an analytical tool, although no data are yet available to back this theory up. The technique is briefly discussed.

When a charged particle is moving in a plane that is perpendicular to a uniform magnetic field (Figure 67) that is in turn perpendicular to a uniform electrical field, the particle follows a cycloidal trajectory. The ions’ path has a
repetition distance, or cycloidal pitch, that is independent of ion energy and the angle of injection into the crossed fields. Given a fixed electrical field \( E \) and fixed magnetic field \( B \), this pitch depends only on the mass-to-charge ratio of the ion. If \( p \) represents the pitch, this may be expressed by Equation (24):

\[
P = 2\pi \frac{E(m/z)}{B^2} \quad (24)
\]

If an ion source produces ions that are forced to enter such a crossed set of fields through a narrow slit, ions of a given mass-to-charge ratio move with a trajectory that comes back to the initial position after moving a horizontal distance equal to the pitch. Again, this is independent of the initial entrance angle of the ion into the field and the initial energy of the ion. The cycloidal mass spectrometer uses fixed electric fields and a collector array to collect a wide band of mass-selected ions simultaneously. The dimensions of the analyzer are potentially small (centimeters).

Small trochoidal mass spectrometers such as the MG2100, from Industrial Scientific Corporation (Oakdale, PA, USA) are suitable for the measurement of residual gas composition in ultrahigh vacuum systems and could potentially be used in applications for environmental analysis. A potential drawback of the FTMS technique is the need for powerful magnets and the interaction of high magnetic fields with instrumentation. There is no published information on the effect of a downgraded vacuum (due to the coupling of a gas chromatograph) on the performance of this instrument and it is, therefore, too early to speculate on potential GC/MS applications.

5.3 Portable Gas Chromatography/Mass Spectrometry Detectors

Over the past few years, GC/MS has emerged from the laboratory and into the field. In spite of its complexity and size limitations, the sheer analytical power of this hybrid separation and analysis technique has helped it earn its place in the field. A number of workers have demonstrated that transportable GC/MS systems can be moved to a field site and operated by bringing samples to the instrument either manually or via long, heated, analytical transfer lines. The next step is to develop field-portable equipment with analytical performances similar to those achieved with laboratory instrumentation.

There is a broad range of commercially available bench-top instruments, including quadrupoles and ion traps. Several specialized MS instruments operating in a mass range up to 1000 Da have been developed for applications for which transportability is a prime requirement. Well-known examples include the Bruker Franzen (Bre- men, Germany) MEM and EM650 systems, originally developed for military applications involving chemical agent detection, and the Viking Spectra Trak system, primarily designed for environmental applications. All the instruments used for field analytical work require only unit resolution.

5.3.1 Portable Gas Chromatography/Mass Spectrometry Detector Based on a Quadrupole Mass Analyzer

Figure 68 shows a view of the Viking Spectra Trak 572 (Viking Instruments Corporation, Chantilly, VA, USA). This instrument is self-contained and requires only the power from an AC line. This transportable GC/MS is configured for GC injection with a capillary direct transfer line. The miniaturized GC oven accommodates standard capillary columns and provides temperature programming and a split or splitless injector. Other options are available and should be checked with Viking Instruments Corp. Figure 69 shows the overall instrument without a cover. The mass analyzer is a fixed-geometry monolithic quadrupole from Hewlett-Packard (Model HP5973A MSD). Figure 69 also shows the vacuum pumps, the GC oven, and the sample introduction hardware. The main instrument features are summarized in Table 15.

5.3.2 The Hapsite

The Hapsite instrument is designed to cover mass ranges from 1 to 300 Da and, therefore, is useful only for the analysis of VOCs. The mixture is first separated by a GC column before being analyzed by a quadrupole filter. One of the particularities of this instrument is that it is self-contained and operates on batteries. The instrument includes the vacuum pump, the carrier gas supply, an internal gas canister for calibration, rechargeable batteries, and all the electronics to control the instrument and acquire and transfer the data to a foreign site.

Figure 68 Spectra Trak 572 portable GC/MS instrument. (Courtesy of Viking Instrument Corp.)
Figure 69 Cutaway view of Spectra Trak 572 chassis. (Courtesy of Viking Instruments Corp.)

The vacuum system is the part of the instrument that typically consumes the most power. This subsystem is also the heaviest portion of the instrument. The Hapsite portable GC/MS instrument manufactured by INFICON (East Syracuse, NY, USA) uses a commercial bulk getter pumping system. In this vacuum subsystem vanadium–iron–zirconium alloy sintered pellets are heated to 200 °C to pump chemically most gases and vapors. The lack of pumping capacity for noble gases represents a problem because of argon accumulation due to small air leaks in the vacuum system. A small secondary ion getter system is added to provide sufficient noble gas pumping. This instrument requires a separate service unit with an AC supply, vacuum pump, and carrier gas supply to prepare the portable unit before field operations. The specifications of the instrument are summarized in Table 16.

5.3.3 Time-of-flight Mass Analyzer

The performance of the TOFMS analyzer is a direct function of flight-tube length. The resolving power of a commercially available instrument with a 2-m flight tube is approximately 500. Various improvements have been developed to reduce the length of the instrument without limiting the flight path. Kore Technology has patented and developed a spectrometer geometry that starts with a ring-shaped ion source with a dimension of 20 cm (8 in) and a mass range of 1000 Da (Figure 70).130

The ions are extracted perpendicular to the ring and deflected inward so that, as they proceed through the spectrometer, each annular bunch of ions converges to a relatively small size by the time it reaches the detector. This allows a relatively large source to be used with a small detector giving parts per billion detection limits. In addition, an aperture can be placed at the crossover to allow mass or energy selection and enhance mass resolution. The specifications of the Kore TOF mass analyzer are given in Table 17.

5.3.4 General Comments

Miniaturized spectrometry is a powerful analytical technique that has found wide use in laboratory and applied monitoring areas. Applications have included planetary orbiting missions (Mars Viking Lander GC/MS), earth orbiting satellites (Atmospheric Explorer satellites and others), manned spacecraft respiratory experiments (Skylab), submarine atmosphere monitors, and commercial, medical, and industrial process monitors. Research efforts in the late 1990s have demonstrated that miniaturized systems can be built with today’s technology.

To miniaturize a mass spectrometer, some trade-offs must be accepted. For instance, it is generally accepted that sensitivity falls off rapidly with increasing mass range and decreasing size and that it is difficult to get it back by increasing gas load, implying a correspondent higher pumping speed and larger pump.

In addition to understanding the parametric relationships for each type of instrument, a practical knowledge of its performance is also essential. Some general comments regarding the various analyzers can be made. For instance, the ion trap is a proven sensitive analyzer with a dynamic range that is more limited than some other systems. The ion trap requires a collision gas to achieve good operation, which places a high gas load on the instrument, affecting the size and type of vacuum pump. The quadrupole mass spectrometer does not have these limitations and operates at lower pressure than the ion trap. It has a larger dynamic range, but is somehow less sensitive and is not as fast as the ion trap.

Although the TOF system may have appeal, there are duty cycle issues that must be understood before its net performance can be determined. TOF operation also puts a lot of burden on the electronics and vacuum system to operate at its optimum. The drift tube also must be folded to reduce the overall dimensions of the instrument. This design may degrade the performance of the instrument.

The ICR instrument must be operated in the Fourier transform mode, which requires highly sophisticated electronics to achieve superior performance. Like other magnetic sector instruments, ICR systems also have electronics problems due to the size of the magnet and to the effect of the magnetic field on surrounding instruments.

Magnetic sectors and trochoidal mass spectrometers also have a duty cycle limitation, but using an array
detector (focal plane detector) could, at least in theory, overcome this limitation. The overall mass range of the instrument could easily be monitored simultaneously. The major disadvantage for field applications is the weight of the magnet.

5.3.5 Example of Field Measurement by Gas Chromatography/Mass Spectrometry

A confidential site in the northeastern United States was characterized as having shallow soil PCB contamination. Previous data suggested the presence of Aroclor 1248 and 1260 in the formerly earthen containment area. Field measurements performed with a portable GC/MS system from Viking Instruments confirmed the identities of PCBs (Figure 71a). Field GC/MS analysis also allowed easy resolution of the Aroclor mixtures detected in many samples, allowing for accurate PCB quantification (Figure 71b). The quality of the measurements is equivalent to or better than those performed in the laboratory, since the elimination of sample transportation reduces the risk of sample deterioration. Turnaround is typically hours instead of days, which can significantly reduce costs.

5.4 Ion Mobility Spectrometry

IMS, like MS, falls in the category of mass dispersion methods. IMS was first described as an analytical method for trace analysis in 1974; since then, its potential for field analysis has received some recognition, especially in the military, for the detection of chemical warfare agents such as nerve gases and blister agents. In addition to these applications, IMS has also been recognized as useful in a number of narrow technical niches for the chemical analysis of vapors. Several broad categories in the development of IMS have been identified:

- a selective sensor in which the chemistry of ionization can be tailored or manipulated for the detection of a specific compound or classes of compounds;
- a stand-alone analyzer for samples of predictable composition;
- a potential catalyst for improving the performance of GC for crude separation.

When the experimental conditions are suitable (low moisture and elevated temperature, ionization mechanism), all chemicals introduced into an IMS system can be ionized, which produces a spectrum of responses. In short, the conversion of molecules to ions at ambient pressure followed by ion characterization is nearly as comprehensive as MS.

The IMS detector has some unique advantages over GC detectors, including MSDs, but also has some limitations, the most serious being its limited dynamic range. In addition, IMS should not be compared with TOFMS. While certain functional similarities exist between TOFMS and IMS, comparisons can create unrealistic expectations for IMS performance. IMS peaks are typically rather broad compared with the range of possible drift times, and the amount of qualitative information available from IMS is less than that from MS and IR spectrometry but more than that from FID and ECD. On the positive side, IMS detectors have been engineered to be truly hand-portable stand-alone units, with a chemistry adapted to specific applications in order to enhance their sensitivity to some compounds. A brief introduction to IMS follows, with emphasis on field applications and equipment. An excellent source of information for this technology is available.
5.4.1 Description

IMS has received a fresh examination in the last few years. The interest in this technique is due to its intrinsic response features (excellent detection limits) when the experimental conditions are suitable (low moisture and elevated temperature) and to practical considerations (size, weight, and power advantages). Interest has also grown, following successful, proven application of IMS technology to significant challenges, including chemical warfare agent sensing, contraband screening, and toxic vapor monitoring.

Figure 72 shows a chemical agent monitor (CAM) unit developed by Graseby Ionics, Ltd. (Watford, Herts, UK). Its simplicity of design, atmospheric pressure operation, universality of response, and ion-resolving capability have enticed both scientists and instrument manufacturers to miniaturize and modify IMS detectors to provide analytical determination of targeted compounds in nonlaboratory environments.

The IMS technique is illustrated schematically in Figure 73. The sample is introduced by means of a carrier gas into a reaction region, where it is ionized. Although positive and negative gas-phase ions for IMS have been produced by a variety of methods, including photoionization, laser multiphoton ionization, thermoionic emission, and corona spray, the most common ionization source is radioactive $^{63}$Ni foil. In the presence of sample molecules these ions undergo ion–molecule reactions to generate product ions. The nature of the product ions depends on the type of ion–molecule reaction that occurs, and early models for their formation can be found. Once formed, product ions are extracted from the ion source region under the influence of an electrical field, and ions are drawn toward an ion shutter. The ion shutter is periodically pulsed, and ions are injected into the drift region.

In the drift region, the ions travel toward the collector still under the influence of the electric field imposed on the entire drift tube. Because ions with different cross-sections travel with different velocities, the ions are separated and arrive at the collector at different times. When ions of different types and mobilities exist in the drift tube, the ions can be separated through differences in their mobilities.

5.4.1.1 Drift Velocity

The ion mobility is characteristic of a particular ion and can provide a means for detecting and identifying vapors. Ion mobilities are determined from ion velocities, which are measured in a
drift tube with supporting electronics. In practice, a vapor sample is introduced into the reaction region of a drift tube where neutral molecules of the vapor undergo ionization, and the resulting ions (product ions) are injected into the drift region for mobility analysis. Mobility $K$ is determined from the drift velocity $V_d$ attained by ions in a weak electric field $E$ of the drift region at atmospheric pressure (Equation 25):

$$V_d = KE$$

Ion velocities are inversely dependent on the effective collisional cross-section of an ion, making IMS a kind of molecular size analyzer. Commonly, electrical fields of 200 V cm$^{-1}$ and mobilities of 1–2 cm$^2$ V$^{-1}$s$^{-1}$ result in ion speeds of 200 to 1000 cm s$^{-1}$ or drift times of 5–20 ms in 4–20-cm long drift regions at ambient pressure. As the reactant ions and product ions are drawn toward and collide with the detector plate, current is registered and a signal is generated as a mobility spectrum (Figure 74a and b). When ions of different types and mobilities exist in the drift tube, the ions can be separated through differences in their mobilities (Figure 74b).

5.4.1.2 Ionization Process Vapors from nearly all chemical classes or functional groups can be ionized through atmospheric-pressure chemical ionization (APCI) processes. However, a given substance can be converted into different product ions, depending on the ionization mechanism. In addition, various product ions can be formed from a substance at a given concentration and temperature, but most of these are fragile clusters that do not survive transit even from the source region to the shutter. Hence in an IMS spectrum, only the stable ions survive and the bulk of all ions survive, sometimes into stable ions. In practice, higher clusters are formed in the source and are rapidly depopulated to protonated monomers and proton-bound dimers in the drift region.

A fortuitous consequence of proton or electron transfers is that molecules form ions that retain much of the original shape and size of the molecules. In addition, product ions rarely dissociate or fragment, since the energetics of the APCI process are weak; mobility spectra thus often comprise only one ion or a few ions with a direct structural association to the original neutral molecule. The extensive fragmentation of molecules in EI ion sources for mass spectrometers does not occur as a general rule in IMS.

Ions are generated in a purified nitrogen or air carrier gas containing a trace of water vapor, by the action of $\beta$-particles emitted from a $^{63}$Ni foil. The primary N$_2^+$ ion resulting from the ionization of nitrogen gas is too short-lived to appear in the IMS trace but begins a series of ion–molecule reactions, principally with nitrogen and trace amounts of water.

In the absence of a sample, the resulting stable ion clusters have been identified as (H$_2$O)$_n$NH$_4^+$, (H$_2$O)$_n$NO$_2^+$, and (H$_2$O)$_n$H$_3^+$. These background ions are called reactant ions because they undergo further ion–molecule reactions with neutral gas-phase analytes to produce analyte product ions. The formation of product ions occurs in the ionization region predominantly by collisions between the reactant ions and the sample molecules. In addition, product ions may be formed through association reactions in which an adduct is made by a weak attachment of a reactant ion to a neutral vapor. A trace organic molecule injected into the carrier gas undergoes reactions with these ions and electrons, forming reaction product ions that show both quasimolecular and simple dissociated ions in their mobility spectra. This method is extremely sensitive and reasonably quantitative. It is capable of detecting 10$^{-12}$ g or less of a compound and can provide identification through the characteristic positive and negative mobility spectra.

Positive and negative ions can be independently observed merely by the choice of the electrical field polarity. Positive product ions are formed mainly through a proton-transfer reaction. Early models for the formation of product ions of positive polarity have been summarized.$^{[145]}$ By monitoring positive reactant ions, one can gain essentially the same information from IMS that is obtained from an FID.$^{[147]}$

![Figure 74](image-url) An ion mobility spectrum is a plot of detector response versus drift time. (a) A reactant ion peak (RIP) and a product ion peak are evident. (b) Productions are shown for two compounds.$^{[139]}$
The formation of negative ions in IMS is closely related to those chemical events that occur in an ECD. Early reviews of the ECD form the foundation for the current understanding of negative ion chemistry in IMS. Two general observations have evolved: the data contained in positive mobility spectra bear a close similarity to those obtained in chemical ionization MS, and the data contained in negative mobility spectra correspond to those obtained with GC/ECD. Interpretation of the data based on this model is available.137

Ions formed in the reaction region are injected as a short pulse (200–300 μm) into a drift tube, where they acquire constant velocities under the influence of a weak electrical field and collisions with a counterflowing neutral drift gas (air or nitrogen). Various ions injected into the IMS drift region will arrive at the Faraday cup detector at different times, as determined by their mass, charge, and collisional cross-section with a drift gas. Consequently, different ion species, even if characterized by the same mass, may arrive at the detector at different times.151

An important variation of IMS ionization that can be used to enhance the sensitivity or selectivity of the technique for particular classes of compounds involves the modification of reactant ion populations by adding carefully controlled concentrations of dopants to the drift gas. For example, Cl⁻ reactant ions have been used to increase sensitivity to explosives, NH₄⁺ reactant ions enhance selectivity to amines, and (CH₃COCH₃)₂H⁺ reactant ions are used to ionize organophosphonates selectively.153,154

In summary, IMS comprises and is governed by two distinct, independent or separate events: gas-phase ionization in air at atmospheric pressure through collisional charge exchanges or ion–molecule reactions and ion characterization using mobilities of gas-phase ions in a weak electrical field.

5.4.2 Instrumentation for Ion Mobility Spectrometry

It is convenient to divide the IMS system into three major sections: the sample introduction system, which is the interface of the instrument with the ambient atmosphere, the drift tube, where ionization and the separation and detection of the ions take place, and the detection device, where the signal is acquired, analyzed, and displayed.

5.4.2.1 Sample Introduction  The use of a nonporous dimethylsilicone membrane barrier to the interface between the IMS system and the ambient atmosphere is the most common way to introduce samples into the IMS instrument, but in addition to membranes, other sample-to-drift tube connections have been made by GC inlets, electrospray, thermal desorption, and pyrolysis. The membrane retards the flux of water and ammonia molecules present in the sampled ambient air, thus limiting the number of polar molecules available for cluster formation. Excessive clustering reduces the resolution of IMS and may lead to erratic behavior of the ion signals. Membrane interfaces are especially important in a portable instrument when the drift tube operates near ambient temperature, as clustering presents a serious problem under this condition. The main advantage of employing a membrane interface is that it makes ambient-temperature operation possible and can lead to a considerable reduction in power consumption and thus in size and weight, which is required for handling instruments. The disadvantages of using a membrane are diminished sensitivity and an increase in the response time of the instrument. Other ways of increasing the selectivity and sensitivity of IMS rely on preseparation by GC and will be discussed later.

Reagent gases can also be selected as a means of increasing the sensitivity and specificity of IMS by preferentially ionizing the target compound or by enhancing the separation of the target ions from the reactant ions without affecting the response time of the instrument. For instance, adding a reagent gas that has a proton affinity just slightly below that of the target eliminates most of the interfering ion signals, and the presence of the target compound is easily detected. For example, monitoring isopropylamine (proton affinity = 218.6 kcal mol⁻¹) using ethylamine (proton affinity = 217.0 kcal mol⁻¹) as a reagent gas should exclude interferences from all compounds that have proton affinities below that of ethylamine.

5.4.2.2 The Drift Tube  The first patented commercial IMS analyzers were created by Franklin-GNO, Inc. The drift tube was made of circular elements biased at different electrical potentials to maintain a uniform electric field gradient of 200–300 V cm⁻¹ along the central axis of the tube. These elements were alternating conducting and insulating guard rings.

Molecules were ionized by a polished β-emitting radioactive ⁶³Ni source inserted into the first guard ring. The shutter grid was of the Bradbury–Nielsens type, in which a potential difference is placed between a set of interdigitated thin wires with a voltage difference applied to each of the independent wires, thus creating a strong electrical field (of about 600 V cm⁻¹) perpendicular to the axis of the field gradient across the drift tube. A collector plate, somewhat like a Faraday cup, was placed close to the collector to increase detection efficiency and to filter out the noise caused by the pulse on the gate, thus improving the signal-to-noise ratio.

The basic design has been modified in several ways. The drift tube is now segmented with a unidirectional flow (Figure 75). With this modification, the sample is introduced into the reaction region just downfield of the
ionization source and is swept by the drift gas through the source. The unidirectional flow drastically reduces both memory effects and residence or response time and clarifies ionization chemistry, thus improving the performance of the cell drastically. The ions are moved down the length of the tube by the electrical field, while the neutral sample molecules that are not ionized spend only a short time in the reaction region before being swept out.

5.4.2.3 Detection Devices and Signal Processing The ion mobility spectrum is a plot of the signal intensity (ion current) as a function of the drift time, taking zero as the time the shutter-grid gate is opened to allow ions to enter the drift region. The most common and simple detection method used to measure the ion current in the IMS drift tube is a collector plate, somewhat like a Faraday cup. The output signal from the collector is, therefore, an analog signal that is digitized and displayed as a digital signal.

There are several basic modes of operation: signal averaging (up to hundreds of spectra are averaged to increase the signal-to-noise ratio), hardware monitoring, and Fourier transform. Another method of registering a signal is through the use of two shutters with boxcar integration. In this technique, a ion shutter near the source region is operated at a fixed frequency of approximately 30 Hz for a conventionally sized drift tube, and the shutter pulse width may be 100–300 µs. After the first shutter is opened, a delay is measured and the second shutter, near the detector, is opened for a short interval and then closed. Only ions with a drift time corresponding to the delay are allowed to pass to the detector. This delay is gradually increased to a maximum, and the spectrum is generated during the sweep of the delay time.

5.4.3 Quantitative Limitations of Ion Mobility Spectrometry

IMS has been shown to be a selective and extremely sensitive detection technique for monitoring vapors or air pollutants. However, systems with membrane-type inlets, such as the CAM, are subject to serious limitations with regard to both qualitative and quantitative performance. Moreover, an ion mobility spectrometer, as with any secondary ionization detector, exhibits a nonlinear response with respect to the concentration of analytes introduced into the ionization chamber. Such a response increases exponentially up to the depletion of the reactant ions that is observed as the disappearance of the RIP peak from IMS trace.

As shown in Figure 76, standard IMS systems are easily overloaded with analyte and have a narrow linear dynamic range. Each IMS trace in Figure 76 was obtained at a different concentration of dimethyl methylphosphonate (DMMP) with a 4-s sampling time in the positive ion mode. DMMP vapor concentrations of 20 and 60 ppb produce only protonated monomer peaks. However, proton-bound dimer and trimer signals for DMMP appear above 130 ppb. Furthermore, the intensities of the protonated monomer and the proton-bound dimer are proportional to the DMMP concentration between 20 and 280 ppb and between 130 and 1700 ppb, respectively. The intensity of the trimer shows a narrow linear response range. In other words, high sample concentrations produce cluster ions that not only reduce the useful linear range but also produce more complex IMS traces.

5.4.4 Hand-held Ion Mobility Spectrometry Instruments

The widest application of hand-held IMS instruments is the detection of chemical warfare agents (Table 18). The CAM made by Graseby Ionics, Ltd. and manufactured under license in the USA by Environmental Technologies Group, Inc. (Baltimore, MD, USA), is slightly larger than a cordless telephone. Weighing less than 1.8 kg, with 38 cm as its longest dimension, this CAM represents an exceptional work of engineering. The drift tube, sampling and flow systems electronics, signal processing, and a simple bar display have been compressed into a...

hand-held module. A civilian spin-off of the CAM, called the airborne vapor monitor (AVM), is also produced by Graseby Ionics, Ltd. A recent development in hand-held IMS instruments is the inclusion of a GC column as a preconcentrator that is interfaced with the AVM commercialized by FemtoScan (Figure 77).

The production of commercial applications is, to a large extent, a spin-off of the military chemical agent detector and monitor program. When discussing industrial and environmental applications of IMS, it is convenient to differentiate between fixed-point monitors and hand-held instruments. The former are used to detect, measure, and monitor a specific compound or a number of chemicals at a fixed location on a continuous basis. The hand-held instruments are generally used as monitors for a short duration at a given spot and are easily transportable from point to point. Hence the fixed-point monitors are useful for obtaining the concentration versus time profile at a given point, whereas the hand-held instruments are useful for obtaining concentration versus location profiles. Hand-held instruments are ideally suited for detecting leaks or hot spots at which the chemical of interest has accumulated.

The major environmental and industrial applications of IMS instruments include monitoring toxic chemicals, stack gases, and chemicals that are considered hazardous to humans or to the environment. To date, few detailed accounts of the performance of IMS have been made public. Applications of IMS can be found in reviews (161–163) (Table 19). A comprehensive list of chemicals that can be monitored by IMS is available; it includes compounds such as toluidine, pyridine, diaminotoluene, dimethyl sulfoxide, glutaraldehyde, methyl salicylate, acetic acid, acetic anhydride, halothane, enfurane, isoflurane, and nicotine.

5.4.5 Partial Review of Published Ion Mobility Spectrometry Applications

The use of IMS for field applications has been described in a number of symposia related to waste monitoring. Some key environmental and industrial applications of IMS have been reviewed. Nickel carbonyl, which is highly toxic with a TLV of 50 ppb, has been targeted. Another application of IMS is monitoring the toxic

chemicals hydrazine and monomethylhydrazine (MMH) at levels below TLVs above 10 ppb. Another advanced environmental application for commercial IMS is the monitoring of hydrogen fluoride at parts per million levels. Another application is the monitoring of highly toxic (TLV 5 ppb) TDI. Unlike industrial and environmental applications, the use of IMS-based technology to detect contraband explosives or drugs does not require quantitative measurements. Because of the high sensitivity of IMS, its specificity, and the fact that it operates at atmospheric pressure, it is apparently a leading candidate for detection of hidden contraband materials. The major problem is getting enough molecules of the target compound into the detector. This problem is most severe with chemicals that have low vapor pressures.

IMS is currently being successfully applied to the problem of the on-line trace detection of plastic and other explosives in airports and other facilities. The methods of sample retrieval consist primarily of batch sampling for particle residue on a filter card for introduction into the IMS system. The sample is desorbed using air as the carrier into the IMS instrument, where negative ions of the explosives can be detected, some as an adduct with a reagent ion such as Cl⁻. Based on studies and tests conducted by different airport authorities, this method seems to work well for low vapor pressure explosives, such as trinitrotoluene (TNT). These are highly adsorptive and can be found in nanogram quantities on contaminated surfaces.

An ion mobility spectrometer is also capable of detecting minute amounts of narcotics with few false alarms and a minimum of operator intervention. Sampling rates of 10 suitcases or passengers per minute have been reported.

5.4.6 Recent Developments in Gas Chromatography/Ion Mobility Spectrometry Techniques

In GC, constituents of a mixture are physically separated by the column and identified from their elution time. With the exception of the mass spectrometer, GC detectors do not provide any information about the chemical identities of the compounds. The most important feature that GC brings to IMS is the individual delivery of compounds to the IMS system, thus reducing the problem of interferences and providing near-ideal ionization conditions. The GC part of the system is usually unsophisticated compared with a laboratory gas chromatograph, and provides only crude separation of the components.

The hand-held IMS instrument shown schematically in Figure 78 is a combination of a successful military IMS system with an inlet developed for sampling ambient atmospheric vapors. The addition of a short capillary column between a specialized valveless inlet and the ion mobility spectrometer allows for the separation of vapors in less than a few seconds.

The pumps, used originally in hand-held IMS instruments to control drift gas and sampling flows, are used to lower the pressure in the drift tube. This results in a pressure drop across the column, and the air is drawn through the column as the carrier gas. The configurations shown in Figure 78 permit only isothermal column temperatures and constitute a prototype hand-held GC/IMS system.
The ability to produce an effective hand-portable instrument depends on achieving several goals: limited sample preparation and pre-separation (short chromatographic column, for instance), lightweight design (simplified design, use of air instead of nitrogen), and high-speed response (just enough chromatography, no baseline separation). The efficiency of the GC column in this example is only 2000–5000 theoretical plates, yet it is suitable for delivering the phosphonate esters individually to the ion source and reducing interference problems.

Figure 79 illustrates some advantages of operating an IMS system in the AVS transfer line gas chromatography (TLGC) mode, compared with the membrane inlet for air analysis of an equimolar mixture of model alkylphosphonates. The IMS trace of the ternary mixture of alkylphosphonates without GC pre-separation (i.e. in the case of a membrane-type inlet) reveals several mixed-ion peaks [e.g. DMMP + diethyl methylphosphonate (DEMP) and DEMP + diisopropyl methylphosphonate (DIMP), etc.] in addition to protonated monomer, proton-bound dimer and trimer formation by particular components (Figure 79, trace A). The IMS trace of the same mixture is presented as trace B, but it was obtained by an average of 32 scans recorded after AVS injection into a 2-m long capillary column. Pre-separation by TLGC introduces each component separately into the ion source. Therefore, the relative intensities of particular component signals reflect the composition of the original mixture, since no mixed-ion peaks or competitive ionization processes are observed. All individual IMS traces recorded after sampling the analyte mixture are presented in Figure 79, traces C, in the form of a pseudo-three-dimensional waterfall graph. Furthermore, a reconstructed transfer line gas chromatogram of this ternary mixture, obtained by summing all ion current intensities at drift times between 5 and 7 ms, is shown in Figure 79 as trace D. It is clear that a 2-m long capillary column provides sufficient resolving power to produce just enough separation of the ternary mixture components within 30 s, simplifying ionization processes and dramatically improving qualitative and quantitative capabilities of the CAM for analysis of mixtures.

The use of short, fast separation columns reduces many problems associated with analysis of complex mixtures. However, under real-world conditions, co-elution of compounds is inevitable in IMS and can complicate the interpretation of spectra. Therefore, part of the optimization should include the chromatographic separation.

5.4.7 Recent Progress in Ion Mobility Spectrometry Technology

The limited linear response of IMS to one or two orders of magnitude is one of the limitations to using IMS as a GC detector. To extend this dynamic range there has been some attempt to operate the IMS inlet on a dynamic dilution sampler. In this concept, the sample intake is pulsed with a fast valve (down to 20 µs) into the inlet against a flow of clean air or nitrogen. The amount of sample entering the inlet is governed by the pulse rate or the pulse width of the valve. In an effective and practical inlet, either of these would be controlled by the RIP intensity from the mobility spectrum. The valve is fully
Figure 79: Comparison of a direct and an AVS GC/IMS inlet mode. A, direct inlet IMS trace of three methylphosphonates (without TLGC pre-separation). B, sum of the 32-ion mobility scans from the GC/IMS traces of the methylphosphonates shown in C; C, quasi-three-dimensional waterfall display of a GC/IMS profile. D, chromatogram of the GC run shown in C.\(^{(160)}\)

open until the RIP intensity falls below a preset value, which then triggers pulsing of the valve.

Figure 80 illustrates the application of the servo-inlet concept. The IMS traces were obtained for various concentrations of DMMP in air and at different sampling pulse durations [called automatic attenuation control (AAC)]. These spectra should be compared with those in Figure 76, where the sample was injected without dilution. In Figure 80, only the protonated monomer is the major peak for DMMP vapor concentrations up to 1700 ppb. This is achieved by specifying the depletion level of the RIP peak (selected in this application as 50% of its background level), and a sampling time of the AVS that should be shorter than the intrinsic broadening caused by the GC/IMS system. Based on these spectra, the dynamic range of IMS is extended over four decades.

5.4.8 General Comments About Industrial Applications of Ion Mobility Spectrometry

IMS is a sensitive detection method with a broad response that has found favor in certain applications, owing to the advantages of some IMS drift tube configurations. The industrial products based on IMS techniques are still limited, probably because the use of these devices requires a meticulous understanding of the measurement process. Both the target chemical and the matrix must be evaluated when considering IMS for an application. IMS limitations and possible solutions to some of its identified problems have been published\(^{(163)}\) and are summarized below:

- The chemical compound to be detected must be in the vapor state and must be ionized in the reaction tube of the IMS system. Some materials, including small hydrocarbons, are not easily ionized with a radioactive source when using water-reactant ions, but may be seen using other ionization techniques, such as charge exchange ionization.
The IMS response varies with the gas pressure in the drift tube. Small atmospheric pressure variations can disrupt measurements and require frequent calibration when IMS is used at high sensitivity.

Ion clouds are formed by stealing charge from the reactant ion, which may significantly change the concentration. This problem is usually corrected by doping the carrier gas stream with a compound that has a proton or electron affinity slightly below that of the compound to be analyzed.

IMS peaks, and particularly the RIP, change position with variation in humidity because of differences in water clustering. In a portable IMS this can be controlled by using a recycling loop of air that is continuously dried by scrubbers.

The limited dynamic range of one to two orders of magnitude is a serious limitation. In addition, the signature of a compound varies with the concentration. Working at a constant concentration (dynamic dilution) close to that used for calibration is an attractive but not yet practical approach to achieving quantitative results over a broad dynamic range.

Water and ammonia, even at low concentrations, can create a change in the performance of the IMS system, which can take a long time to recover.

Although IMS was begun over 25 years ago as an analytical technique, the technology is still in a nascent stage of development. The current implementations of IMS have shown technology “fences” rather than fundamental limitations. For example, high-resolution IMS drift tubes of a small size have been demonstrated in Germany and, recently, the injection pulse width has been recognized as critical, opening up a broad area of research and potentially new products. In conclusion, significant technical improvements can be expected in the near future and, as the price of IMS instrumentation decreases, a broader use of this technology for field industrial applications will also be seen.

Microelectromechanical Systems Technology Applied to the Miniaturization of Field Instrumentation

Michel Goedert and William Higdon
Hewlett-Packard Laboratories, Palo Alto, USA

1 Introduction

MEMS technology has emerged since the late 1950s as an outgrowth of the semiconductor industry. Research laboratories in academia and industry have studied potential commercial MEMS applications and technologies; however, progress has been slow and sometimes arduous compared to the fast-paced electronics revolution. MEMS exploits many more physical, chemical, and optical effects than does pure electronics, and the design and fabrication effort for MEMS is correspondingly greater.

The piezoresistive effect in silicon was discovered at Bell Laboratories in 1954, allowing silicon to be used for sensing pressure and force. In the 1960s the first silicon-diaphragm pressure sensors were introduced, and by 1979 they had penetrated the automobile market as manifold absolute pressure (MAP) sensors. Since then other MEMS devices have made strides into automotive, medical, ink-jet printer nozzle, and industrial markets.

In the early 1970s NASA (National Aeronautics and Space Administration) funded Stanford University in California to develop a miniature high speed GC intended for use on the two Mars Viking missions in 1975 and 1976. NASA wanted a small lightweight analytical instrument that could operate with low resource consumption and a sensitive detector, but be rugged enough to withstand the gravitational forces of a rocket launch and a Mars landing. A breadboard instrument was developed to demonstrate the feasibility of this technology applied to measurement of atmospheric gases. For the first time a design integrated a gas injector, a small column and a detector in one silicon wafer. The GC-on-a-chip was born.\(^{(1)}\)

This GC\(^{(2)}\) constituted a technology breakthrough and a new trend in the future development of analytical instruments. On the down side, the “GC chip” itself was only a part of the overall GC instrument; data handling equipment, gas supply and control were all external to the silicon wafer.

The Stanford GC project led in 1983–1998 to the development of portable GCs for industrial applications by MTI Analytical Instruments; those products were acquired by Hewlett-Packard (Palo Alto, CA) in 1998, and their development continues.

These miniature GC systems illustrate how MEMS technology can provide miniaturization and unique performance advantages, and how silicon micromachining applied to analytical instrumentation provides advantages over precision machining when small dimensions are crucial, as is often the case in medical, analytical or biological applications.

This paper explores the miniaturization of analytical instruments using emerging microelectromechanical systems (MEMS) technology. MEMS provides an enabling technology base for miniaturization of many kinds. It has grown in parallel with the growth of the semiconductor industry since the discovery of silicon piezoresistance at the Bell Laboratories in the early 1950s, and borrows many principles and techniques from silicon “wafer fabs”. The technology is one of several that promises to revolutionize our lives in the 21st century.

We review some of the processes developed to fabricate MEMS parts and give examples of components developed with this technology. Finally, we describe how this technology has been used to develop a portable gas chromatograph (GC) and other chemical instrumentation for the detection of gases and vapors in the field. We show, with experimental results, how analytical instrumentation can benefit from MEMS technology.
Less visible than the GC on the chip, but economically more successful because of higher volume of production, other silicon micromachined components such as inkjet heads and sensors used by the automotive industry were also introduced at about the same time.

In a complex electromechanical environment such as a car, the need for effective, accurate, reliable and low-cost sensors is pressing. This is why the automotive industry accounts for the largest share of the market for MEMS silicon sensors. The automotive industry recognized many years ago that a smarter car was inevitable to meet strict US Federal requirements to protect passengers and the environment. Low-powered semiconductor devices and rapid advancements in computers made it possible to place sensors throughout the automobile to monitor its wellbeing. These sensors continuously send status reports to the onboard computer which controls actuators to maintain predetermined specifications. Cars now have dozens of MEMS transducers monitoring everything from engine combustion and transmission temperature, to oil and water pressure, to accelerometer devices that inflate air bags. Fuel injector nozzles are MEMS devices that enable the engine to operate at peak performance. These devices have made it possible to keep the cost of automobiles at a reasonable level while dramatically increasing their performance and longevity.

Many manufacturing facilities use MEMS technology in the multiplicity of sensors throughout their processes. Air conditioning systems use MEMS flow sensors and temperature sensors to control the environment. Navigational gyroscopes and global positioning systems (GPS) are also MEMS devices. Manufacturers of analytical instruments are also benefiting from sensor development and are providing better and cheaper control and measurements of fluids. Unfortunately, MEMS device development is much slower than microelectronics in general, making them bottlenecks for even further performance and cost improvements of systems.

2 GROWING IMPORTANCE OF MICROELECTROMECHANICAL SYSTEMS

The total USA market for MEMS in 1996 was approximately $1 billion in revenues, an increase of 12% over the revenues for 1995. Revenues are expected to grow steadily through the turn of the century. The MEMS military and aerospace market is by far the smallest of the market segments. The significance of this market is reflected in the Department of Defense’s (DoD) current initiatives in funding many MEMS research activities. The aerospace portion consists of sales generated from accelerometers and pressure sensors used in commercial aviation in applications such as altimeters, barometers, collision avoidance systems, navigation systems, and cabin pressure. This segment represented $62.2 million in revenues and 5.8% of the overall MEMS market revenues in 1996. The MEMS automotive market is a significant component of the MEMS industry and is one of the market drivers associated with the establishment of MEMS as a viable commercial technology. Most of this segment consists of sales from airbag accelerometers and pressure sensors, and MAP sensors. In 1996, the segment represented $354 million in revenues – 33% of total market revenues.

Along with automotive, industrial, and ink-jet markets, the MEMS medical market has facilitated MEMS success to date. The bulk of the medical market is made up by the sales of disposable blood pressure sensors. The USA MEMS medical market totaled $164.4 million in revenues in 1996, representing 15.3% of the total MEMS market. The information technology (IT) market comprises ink-jet printer cartridges and MEMS displays. In 1996, the IT portion totaled revenues of $400 million.

3 BASIC MICROELECTROMECHANICAL SYSTEMS TECHNOLOGY

MEMS technology plays an important role in the very practical science of miniaturization, but is often associated only with silicon. Mechanical properties of silicon are unique and well established, but other materials, such as insulators, can also be used for MEMS fabrication. MEMS technology, either silicon or insulator based, when applied to portable chemical instrumentation, is a unique tool used to produce three-dimensional (3-D) structures most often from two-dimensional photographic patterns. These parts can have etched cavities, microchannels, or other fluid conduits, and are formed by adding layers of materials that are fused together. The results are structures that can be designed to sustain vacuum or high pressure over a wide span of subambient or elevated temperatures. Thin layers of metals can also be evaporated on insulated suspended structures to provide sensing elements used, for instance, for the fabrication of gas sensors. MEMS techniques can be complex and costly to implement, but are able to produce unique, miniaturized and very versatile parts.

To appreciate fully the advantages and limitations of MEMS, some basic aspects of integrated circuit (IC) technology will first be reviewed. We will describe the most important IC processes used to produce MEMS structures, i.e. photolithography, wet and dry etching, material addition, and material bonding. We will also describe processes used most exclusively for MEMS. For instance, screen printing has a great value for low-volume applications such as dedicated sensors. Another
emerging application is LIGA, the German acronym for X-ray lithography, electrodeposition (galvanoformung), and molding (abformtechnik), which is a sophisticated approach to producing structures by sculpting them in 3-D in thick layers of photosensitive material. It is based on high-aspect-ratio lithography and plating.

This review of MEMS techniques is far from complete; our intent is to show the possibilities of this technology with a limited number of practical examples. The interested reader will find some excellent books on MEMS. Madou\textsuperscript{13} gives useful information about a broad range of applications. Reviews of MEMS technology trends\textsuperscript{14} or applications are periodically published in specialized journals such as Sensors and Actuators B (published by Elsevier). In addition many internet sites contain good descriptions of IC fabrication and MEMS fabrication.

3.1 Photolithography

Photolithography was first developed by a Frenchman named Joseph-Nicéphore Niépce in 1822. The word “photolithography” comes from the Greek words lithos (stone) and graphein (to write). The process we know today was first used in 1950 to produce ICs on silicon wafers. With the advent of ICs, the process of patterning smaller and smaller features onto silicon and gallium arsenide (GaAs) wafers led to ever more sophisticated technologies that are still evolving today. Millions of devices can perform an array of functions at high speed on a few square millimeters of silicon. However, the major difference is that semiconductors use two-dimensional photolithography (on the x- and y-axis), while MEMS devices typically use a third z-axis to be able to create 3-D features.

Photolithography is the first basic tool of MEMS processes. In its principle it is simple: ultraviolet (UV) radiation shines through a piece of glass covered with a predetermined opaque chrome pattern (called a “photo mask plate”) onto a thin film surface of photosensitive organic polymeric (called “photoresist”).\textsuperscript{15} The pattern, which is on the mask plate, is reproduced on the exposed area of the silicon wafer (Figure 1).

The photoresist thus exposed changes its molecular character from the nonexposed areas and is then susceptible to development by solvents. The solvents remove only the exposed areas in the case of a “positive resist” or the nonexposed area of a “negative resist”. After this step, the bare oxide layer on the silicon wafer is exposed and ready for the next step of the process. The unexposed areas retain a protective layer of photoresist that shields them from the next process step. The thin layer of silicon oxide is removed where it is exposed, leaving bared silicon. Features with resolutions of less than 0.25 µm can be achieved.

![Figure 1](image-url) Basic principle of photolithography. Negative resists become less soluble in developer when they are exposed to radiation, and positive resists become more soluble after exposure and thus allow “positive” or “negative” patterns.

3.2 Silicon Etching

Another important step of MEMS processing technology is the etching after the masking operation. Etching is done to create cavities, holes or modify the surface of structures. Etching can be done using chemicals (wet etching), plasma (dry etching) or both. Wet etching can be isotropic, meaning that the etch rate is independent of the crystal orientation of the silicon, or anisotropic (orientation dependent) with different rates in different crystal directions within a single-crystal piece of silicon according to a set of directions which is determined by the orientation of silicon used.

When ordering silicon, the crystal orientation must be specified. The most common orientation used in the IC industry is the (100) orientation but MEMS uses (110) wafers as well. Some definitions are necessary to understand the difference between these orientations. Silicon has a diamond-lattice crystal structure. Each silicon atom has four nearest neighboring atoms to which it is covalently bonded. The principal axes in a crystal can also be used to develop a notation to define specific directions and planes (Figure 2), termed “Miller indices”.\textsuperscript{16} These are a series of small integer numbers enclosed in caret, brackets, parentheses, and braces. For example, [111] denotes a specific direction, whereas (111) denotes the family of all eight directions equivalent to [111]. A (100) notation denotes a particular lattice plane, and {100} denotes all the planes crystallographically equivalent to (100).
The processing characteristics and some material properties of silicon wafers depend on the orientation. The (111) planes have the highest density of atoms on the surface, so crystals grow most easily on these planes. Mechanical properties such as tensile strength are higher for (111) directions. The module of elasticity also shows orientation dependence. Processing characteristics such as oxidation are similarly orientation dependent. For instance, [111] planes oxidize faster than [100] planes, because they have more atoms per unit surface area available for the oxidation reaction to occur.

3.2.1 Wet Etching
Wet etching still predominates over dry etching in many situations. Wet etching of silicon results in atomically smooth surfaces and sharp edges that cannot be obtained with dry etching. It is also cheaper and is usually considered environmentally friendly. Figure 3 illustrates schematically the difference between isotropic and anisotropic etching on a (100) oriented wafer. In isotropic etch (Figure 3a) the silicon is etched uniformly in all directions and at the end the cross-section of the structure is roughly semicircular. Note also that the silicon is removed under the mask (undercut) and therefore the final dimension of the structure will be larger than the dimension defined by the mask. With anisotropic etching, the lateral etching is much smaller than the vertical etching. The cross-section of the structure at the end looks like Figure 3(b). Etching stops when the two (111) planes meet and the undercut is almost negligible. The angle between the top and the side of the channel is a constant (54.74°) and corresponds to the angle between (100) and (111) planes. There are two important consequences. The first is that with this etching approach it is not possible to etch parallel walls with a (100) oriented silicon wafer. The second consequence is that the maximum depth of the channel is set by the opening of the mask. Finally, by using (110)-oriented silicon, straight-walled grooves are formed (see Figure 3c). In this way 0.6-µm wide openings on 1.2-µm centers and 600-µm deep have been made. The choice of crystal orientation, therefore, is generally not left to the discretion of the crystal grower, but is a device design consideration which depends on the structure.

Table 1 gives a brief summary of properties of some chemical etchants applied to silicon. HF acid and KOH are two popular etchants used for the microfabrication of parts. Etching with HF gives isotropic results (same etching rate in all directions) with an etch rate of approximately 3.0 µm min⁻¹. KOH is also orientation dependent, but exhibits a high anisotropic etching ratio (400:1) of (110) to (111) and, for this reason, is useful for groove etching. A disadvantage of HF is that it etches SiO₂ at a rate that limits its use as a mask when deep etching is considered. In structures requiring long etching times, silicon nitride (Si₃N₄) is the preferred masking material.

3.2.2 Dry Etching
The major advantage of dry etching is that it is directional for most materials. Dry etching gives more control, in terms of anisotropy, but is also more expensive and complex to implement than wet etching. Two dry etching methods are commonly used: reactive ion etching (RIE)
and ion milling. Both methods are somewhat directional. With RIE, the surface is bombarded with high-energy ions creating radicals which react with surface atoms. With ion milling, higher energy neutral atoms physically sputter material from the surface. When the bombardment is perpendicular to the surface, the ratio of the depth to the width of etching, defined as aspect ratio, is generally higher than 50:1. A magnetically confined gas discharge is obtained between a thermoionic cathode and a concentric-anode cylinder. To extract the ion beam from the discharge region, a potential difference is applied between a pair of grids with aligned holes. The ions are injected into the working space as a well-collimated energetic beam. The beam is made neutral by extracting low-energy electrons from an auxiliary thermoionic cathode so that it can be used for sputtering insulators as well as conductors.

Reactive plasma etching is another technique which offers several important advantages, when dry etching is considered. In contrast to sputter etching, large differences in etch rates for different materials can be obtained. With this technique, the substrate is exposed to plasma of a reactive gas. Since the ions are not highly energetic, sputtering is not in itself an important surface-removal mechanism. Rather, the reactive gas components appear to be first absorbed on the surface, where they are dissociated by electrons or ion bombardment from the plasma. Then they react with the film material, forming a gaseous product molecule. The reaction products are desorbed as gases and pumped away. Anisotropic etching can occur because the impingement rate on the horizontal surface is much greater than at the side walls at the low pressures used, where the mean free path of the molecules is typically much larger than the depth to be etched. Because of the chemical nature of the process, a high degree of control over the relative etch rates for the film, resist, and substrate can be obtained by the choice of suitable materials.

### 3.3 Material Deposition

Material deposition used for MEMS processes includes the addition of a wide range of organic and inorganic materials. Additive processes involve surface modification such as ion implantation, annealing or deposition. Solids can be deposited from a liquid, plasma, gas, or a solid state. In the deposition methods from the gas phase two categories can be distinguished, a direct line-of-sight deposition technique called physical vapor deposition (PVD) and a diffuse-convective mass transfer technique such as chemical vapor deposition (CVD). PVD techniques include evaporation, sputtering, molecular beam epitaxy, and laser ablation deposition. Plasma-enhanced CVD, atmospheric pressure CVD, low-pressure CVD, very low-pressure CVD, metalorganic CVD and spray pyrolysis are some of the CVD techniques used with MEMS.

Among PVD techniques, thermal evaporation is one of the oldest thin film deposition techniques. Evaporation is based on boiling off a heated material in a vacuum. Evaporation is used to produce films of high purity and known structure at a high rate of deposition (typically 0.5 µm min⁻¹ for Al). Sputtering is preferred over evaporation for several reasons: there is almost no limitation in the choice of materials to be deposited, in-line sputtering equipment is available when successive depositions have to be done, in situ cleaning can be done with sputter etch, the adhesion is excellent, and the deposition can be done over larger areas. The major negative aspect is the high cost and complexity of the equipment.

CVD is another useful tool used for the microfabrication of MEMS structures. CVD is used to produce low-temperature film such as oxides and silicon nitride films. One of the challenges of any surface-micromachined MEMS structure is to limit the residual stress of the film. If we take, for instance, the fabrication of a conventional flow sensor, the heating and sensing elements are suspended on a bridge of silicon nitride to limit the thermal losses between the sensing element and the thermal ground. If the residual stress is not negligible at the operating temperature, the supporting structure will buckle and break. CVD is a very useful tool and enables the user to control the residual stress of the film during deposition.
3.3.1 Silk-screening or Screen Printing

Screen printing falls in hybrid technology rather than MEMS but is worth mentioning because it presents a cost-effective means of depositing a wide variety of films on planar substrates for low-volume production. A paste or ink is pressed onto a substrate through openings in the emulsion of a stainless steel screen. The paste consists of a mixture of the material of interest, an organic binder and a solvent. The organic vehicle determines the flow properties of the paste. The bonding agent provides adhesion of particles to one another and to the substrate. The active particles make the ink a conductor, a resistor, or an insulator. The lithographic patterns in the screen emulsion are transferred onto the substrate by forcing the paste through the mask openings with a squeegee.

Inks have been developed for sensor applications. For example, pastes incorporating Pt, Pd, and Sb dopants have been developed for the construction of high temperature (>300 °C) gas sensors for reducing gases. Thick metal films have been deposited on alumina to form the active material in low-temperature (<180 °C) gas sensors. For biosensor applications, thick-film technology based on pastes that can be deposited at ambient temperature is crucial. Special grades of polymer-based paste have been developed for electrodes, but are applicable to other MEMS structures such as chemical sensors.

Screen printing forms an excellent alternative to thin-film technology when size does not matter but cost in small production does. Biomedical applications fall into this category. Thin-film technology offers better resolution. The finish of the film is also smoother and more reproducible.

3.3.2 X-ray Lithography, Electrodeposition and Molding Technology Applied to Microelectromechanical Systems

The LIGA technique involves high-energy X-ray lithography of thick photoresist from micrometers to centimeters and development to make a resist mold. By applying galvanizing techniques the mold is filled with a metal. The resist structure is removed and metal product results. Alternatively, the metal part can serve as a mold itself for precision plastic injection molding. Several types of plastic molding processes have been tested, including reaction injection molding, thermoplastic injection molding, and hot embossing. The so-formed plastic part, just as the original resist structure, can serve as a mold again for fast and cheap production since it does not rely on a new X-ray exposure. LIGA enables new building materials and a wider dynamic range of dimensions and possible shapes to be used.

LIGA relies on wet chemical plating technology to deposit metals on plastic or silicon. Plating allows thick deposition of metal (up to hundreds of micrometers) on almost any conductive and nonconductive substrate. Lists of plating baths and operating conditions are available in the literature.

X-ray lithography is used with LIGA processes because of its superior performance over optical lithography. X-ray lithography uses a shorter wavelength and a large depth of focus and is well adapted for use with 3-D microstructures for these reasons. Reproducibility is excellent and results are independent of substrate type and surface reflection. The aspect ratio obtainable, defined as the ratio of depth to width of the structure, is typically 100. The major drawback of LIGA is the high cost of the equipment necessary to produce the mold.

A typical LIGA process is shown in Figure 4 as an illustration of a nonsilicon process used to produce MEMS structures. A thick photoresist of up to 1 mm is applied on to a conductive substrate and is then exposed to X-ray radiation from a synchrotron source through a high contrast X-ray mask (Figure 4a). The exposed photoresist is then developed, resulting in the first copy of the high-aspect ratio structure (Figure 4b). The whole structure is electroplated beyond the thickness of the developed photoresist (Figure 4c). After separation from the mask, a complementary metallic mold is formed (Figure 4d). A conductive plate is attached and plastic is injection molded into the metal part (Figure 4e). The metal is separated from the molded structure (Figure 4f). The molded structure is used to electroplate replicas of the original metal part, which in turn can be used to make multiple copies of the injection-molded parts (Figure 4g). The LIGA process is expensive and difficult to develop. However, it should offer the advantage of producing large quantities of parts at low cost. The dimensions of parts obtained by this process in research and development facilities exceed 1 mm with a resolution of a few micrometers. The industrial applications of LIGA techniques have still to be demonstrated.

3.4 Bonding of Microelectromechanical Systems Structures

Most MEMS structures require some type of wafer bonding or cavity sealing, either with glass or with another silicon wafer. We will describe some of the current processes most used in the industry.

3.4.1 Bonding Silicon to Silicon or to Pyrex®

The use of silicon to develop MEMS parts for pneumatic applications requires that these parts be encapsulated. There are several approaches used today, one to bond silicon to silicon and the other to bond silicon to Pyrex®. One technique used is field-assisted thermal bonding.
OBJECTIVES

MEMS TECHNOLOGY APPLIED TO MINIATURIZATION OF FIELD INSTRUMENTATION

Injection moulding

at a temperature of 450–550

A dc voltage of approximately 50 V through the substrates

surface of one of the wafers. Bonding happens by applying

bonding between two silicon wafers can also be achieved

to obtain the irreversible bonding. A variant of the anodic

clamp the pieces locally, conforming the two surfaces to

interface results in a high electric field across the air gap

the bulk of the glass. The depletion of positive ions at the

positive ions away from the glass–silicon interface into

applied to the glass, ionic conduction causes a drift of

about 400 

to the glass. For wafers of small dimensions the metal

oxides covering the wafers. Wafer bonding may be

with a technique called silicon fusion bonding. This direct

bonding is based on a chemical reaction between OH-

groups present on the surface of the native or grown

oxides covering the wafers. Wafer bonding may be

achieved by placing the surfaces of the two wafers in close

contact and inserting them in an oxidizing ambient at a

temperature greater than 800°C. Higher temperatures

(above 1000°C) are usually required to obtain voidless

and high strength bonding.\(^{(31)}\)

Another attractive technique is eutectic bonding. The

Au–Si eutectic bonding takes place at a temperature of

363°C, which is well below the melting temperature of

the individual component of the alloy. The bond is

irreversible and strong.\(^{(32)}\) There are other eutectic alloys

applicable and their choice is determined by the maximum

temperature that the device can sustain without damage.

4 EXAMPLE OF PROCESSING OF MICROELECTROMECHANICAL SYSTEMS COMPONENT

The typical process steps of MEMS are shown in Figure 5.
The final MEMS structure could be part of an ink-jet

nozzle. More examples of this technology can be found in

the literature.\(^{(13,20,33)}\)

The first step (Figure 5a) consists of growing an oxide

layer, usually silicon oxide, on both sides of the silicon

wafer. This layer of oxide will act as a masking layer during

etching. Silicon dioxide is produced by heating the silicon wafer to between 900 and 1150°C, in a stream

of water vapor, or pure oxygen at atmospheric pressure.

Figure 4 Typical LIGA process. (a) Deposition of a thick layer of

photoresist and synchrotron X-ray exposure, (b) develop,

(c) electroplating operation, (d) complementary mold, (e) injection molding, (f) mold separation, (g) electroplating, (h) part separation.\(^{(22)}\)

A glass slide (Pyrex\(^*\) #7070 or #7740 from Corning) is

placed over a polished wafer, the assembly is heated to

about 400°C and a high voltage (~1000 V) is applied
to the glass. For wafers of small dimensions the metal

contact may be a single point probe located near the

periphery of the wafer. Since the negative electrode is

applied to the glass, ionic conduction causes a drift of

positive ions away from the glass–silicon interface into

the bulk of the glass. The depletion of positive ions at the

interface results in a high electric field across the air gap

between the two plates. Electrostatic forces effectively

clamp the pieces locally, conforming the two surfaces to

obtain the irreversible bonding. A variant of the anodic

bonding between two silicon wafers can also be achieved

by depositing a thin layer of borosilicate glass on the

surface of one of the wafers. Bonding happens by applying

a dc voltage of approximately 50 V through the substrates

at a temperature of 450–550°C.

Silicon wafers can also be directly bonded to silicon

with a technique called silicon fusion bonding. This direct

bonding is based on a chemical reaction between OH-

groups present on the surface of the native or grown

oxides covering the wafers. Wafer bonding may be

achieved by placing the surfaces of the two wafers in close

contact and inserting them in an oxidizing ambient at a

temperature greater than 800°C. Higher temperatures

(above 1000°C) are usually required to obtain voidless

and high strength bonding.\(^{(31)}\)

Another attractive technique is eutectic bonding. The

Au–Si eutectic bonding takes place at a temperature of

363°C, which is well below the melting temperature of

the individual component of the alloy. The bond is

irreversible and strong.\(^{(32)}\) There are other eutectic alloys

applicable and their choice is determined by the maximum

temperature that the device can sustain without damage.

4 EXAMPLE OF PROCESSING OF MICROELECTROMECHANICAL SYSTEMS COMPONENT

The typical process steps of MEMS are shown in Figure 5.
The final MEMS structure could be part of an ink-jet

nozzle. More examples of this technology can be found in

the literature.\(^{(13,20,33)}\)

The first step (Figure 5a) consists of growing an oxide

layer, usually silicon oxide, on both sides of the silicon

wafer. This layer of oxide will act as a masking layer during

etching. Silicon dioxide is produced by heating the silicon wafer to between 900 and 1150°C, in a stream

of water vapor, or pure oxygen at atmospheric pressure.

Figure 5 Main steps of a basic MEMS process. (a) Growth of a

thin layer of silicon oxide on the silicon wafer (typically 1000 Å).
The wafer is heated in a steam of water vapor, (b) photoresist

spinning (typically 1 µm), (c) photolithography, (d) opening of

a window in the silicon dioxide with acid and removal of

photoresist, (e) chemical etching of structure either with acid or

with plasma, (f) dicing parts with a diamond saw.
The thickness of the oxide varies between 20 Å (native oxide) to several thousands of angstroms. Other thin layers of material such as silicon nitride can be deposited.

During step 2 (Figure 5b), the photoresist is deposited, usually on both sides of the wafer. Photoresist chemistry is a science in itself with a multitude of variations to achieve specific results. The process engineer can achieve different results by manipulating variables from the use of either negative or positive resist, light exposures to create over and under development doses, as well as using various resist thickness from microns to millimeters. Usually the photoresist is spun at speeds varying from 1500 to 8000 rpm using centrifugal force to flow the liquid evenly across the surface of the wafer. Acceptable variance in thickness for a 1-µm thick film of photoresist is typically ±10 Å (±0.1%) from wafer to wafer. Once the photoresist has been applied, the wafer is “soft-baked” at a temperature between 75 and 100 °C for approximately 10 min. This prebake process drives off some of the solvents and stress relieves the wafer. It also promotes adhesion of the photoresist to the wafer.

Photolithography is done during step 3 (Figure 5c). After the soft-bake process, the resist-coated wafer is placed onto a projection aligner. Using the wafer “flat” to assure proper positioning, the wafer is precisely aligned to within a few micrometers of the mask. The UV lamp illuminates, passing through the unpatterned areas of the photomask and exposing the photoresist film on the wafer. The pattern on the photomask is transferred to the photoresist, changing the molecular structure of the polymeric material in those areas exposed to the light. The areas that have been exposed will now react with the development solvent. These areas will soften and dissolve in the development solvent, opening the designated region down to the surface of the wafer. The unexposed portion of the wafer will remain solid to protect the wafer during either the etching process or adding of material. The wafer is “hard baked” to drive off more solvents and increase the hardness of the photoresist. The patterned wafer is then developed with solvents exposing the oxide layer.

The silicon dioxide is etched and the residual photoresist removed during step 4 (Figure 5d). The oxide on the surface of the wafer is usually etched with acid only at the location exposed during the previous step. All the other locations are still protected by hard photoresist. Now that the windows on the oxide layer have been opened, the remaining photoresist needs to be removed by using either wet or dry processing called “stripping”.

There are several ways to strip photoresist from the wafer using commercial resist strippers. H₂SO₄ (sulfuric acid) based products are commonly used to wet strip the photoresist from the wafer without attacking the wafer’s surface, while dry stripping is an oxygen plasma process. “Ashing” the wafer after the resist strip helps to remove any remaining photoresist residue. This process is accomplished by putting the wafer into a plasma chamber and exposing the wafer to a mild oxygen plasma treatment. The dry stripping process removes all the remaining photoresist on the wafer, leaving the pattern formed during processing. This dry stripping process has become more popular, as it poses fewer disposal problems with toxic, flammable, and dangerous chemicals.

At this point, the silicon wafer is ready for etching.

Step 5 (Figure 5e) shows an example of anisotropic etch on (100) surface orientation. In this example the hole does not go through the silicon.

If there are several masks in the process, steps 2 to 5 are repeated to create the final device.

Step 6 (Figure 5f), the final step, consists of cutting the wafer into individual components called “die” by using a diamond bladed dicing saw. The MEMS part is ready to be packaged.

The above process is typical for developing patterns on the surface of a silicon wafer. However, other processes and materials are being used to develop precision structures in plastics, stainless steel, copper, or any material that can be etched with a solution or plasma process. Photolithography enables the creation of multiple small features within a device and repeat this pattern across the surface of the material of interest. The reason silicon wafers are most widely used is because the expertise and documented history created over many years make them a known quantity in the design of new devices. Complicated structures can be designed more easily when using known processes that create known results. However, in the MEMS world, there are many researchers developing new process methods for various materials. As an example we should mention “Lab-on-a-chip” technology developed for biological instrumentation which relies on microfluidics advanced sensors. Microfluidics chip technology enables an increase in the number of chemical reactions that can be performed concurrently. They are expected to affect optimization of reactions in combinatorial chemistry, drug screening, and polymerase chain reaction (PCR) DNA amplification where speed, precision and cost of reagents are important. The development of a “Lab-on-a-chip” relies on the use of miniaturization technology in plastic parts which is equivalent to what has been done with silicon for parts.

Another emerging MEMS technology used to form devices is a German process called “LIGA”. This process has been described in section 3. In addition, there are other micromachined techniques that have demonstrated usefulness for certain specific applications: deep reactive-ion etching (DRIE) of silicon, microelectrodischarge machining (µEDM), laser micromachining, and polymer stereolithography.
MEMS TECHNOLOGY APPLIED TO MINIATURIZATION OF FIELD INSTRUMENTATION

How is MEMS different from semiconductor processing? Semiconductor fabrication is a two-dimensional process (surface processing) that removes and replaces precisely patterned materials on an X and Y planar surface. MEMS is a 3-D process (bulk processing) that removes and replaces precisely patterned materials, but also creates Z-axis etching to create bridges and suspended beams by using undercut or etching techniques. Not only can MEMS technology create 3-D structures, it can also use the integration of semiconductor technology to create smart mechanical devices. Complementary metal oxide semiconductor (CMOS) technology can add electronic capability to a MEMS mechanical structure to create a new dimension of device development. The pervasiveness of automotive passive restraint systems has emphasized the need for improving system reliability while simultaneously reducing the cost and size of the system. An accelerometer that utilizes silicon micromachining and a CMOS process, along with low cost plastic packaging, supports the requirements of the next generation of automotive passive restraint systems.\(^{38}\)

5 APPLICATIONS OF MICROELECTROMECHANICAL SYSTEMS TO PORTABLE INSTRUMENTATION

During the 1990s there have been numerous attempts in the military and in the private sector to develop microstructures based on MEMS for field applications. One of the most obvious reasons is to reduce the size and weight of these microstructures and to build truly portable systems. The results of space exploration, for instance, have emphasized that cost effectiveness and highly focused mission objectives were necessary to increase the number of missions. MEMS is one of the promising key enabling technologies to create cost-effective, miniaturized, robust, and functionally focused spacecraft for both robotic and human exploration programs. Just to cite a few of them, examples of MEMS devices under development include microgyroscopes, microseismometers, microhygrometers, quadrupole mass spectrometers (MSs), and micropropulsion engines.\(^{29,39,40}\)

Analytical chemistry instrumentation is also on the verge of a revolution. More sensitive detection techniques permit smaller sample sizes and when combined with new concepts based on micromachining and microfluidics, facilitate the control and handling of gases and fluid samples at low cost with batch processing of parts (Figure 6). All these factors are contributing to the renewed interest in and vast potential impact of microinstrumentation. Microsensor technology has paved the way for a new generation of vastly more powerful microsensing systems.

There are many examples of successful applications of MEMS to microsensors as we will see in the next section on gas sensors. These microsensors and microinstruments, are already here and are going to change the way we think about chemical analysis and chemical analysis laboratories.\(^{41–43}\) In the section on portable GCs we will give a detailed description of an instrument based on MEMS.

Although beyond the scope of this article we should also mention that miniaturization is not only for gas phase analysis but is also applicable to liquid phase analysis and biochemical measurements. Miniature biomedical instruments include moving sample, wash, and calibration fluid through small pneumatic connections, controlling the temperature of the fluid, getting the sample into and out of the instrument, providing fresh viable reagents, and detection. All these operations are performed on a lab-on-the-chip and have to be done at low cost. Most of the technology developed to-date has been around the use of plastic injection and hot stamping\(^{44}\) rather than silicon micromachining.

Optical sensors are also an important part of the industry that MEMS have transformed. New concepts and practical issues for accomplishing complete miniature sensor modules for chemical and biochemical applications, which are at the same time small, highly sensitive and stable, are being developed. The novelty of the approach is mainly based on using different types of smart planar optical transducer (SPOT) chips, which not only carry out the task of conventional integrated optical transducers, but also perform additional functions for which peripheral equipment is otherwise needed. The emphasis is on pointing out and discussing the most important aspects for refractometric modules. Different approaches

Figure 6 Example of batch processing of 4-inch wafers yielding a large number of MEMS parts. (Reproduced by courtesy of Hewlett-Packard Company.)
and sensor types are compared with respect to fulfilling the requirements for practical applications. New results concerning the use of multilayer waveguides and the implementation of novel modules are possible.

Whatever the type of application there are several important key issues which have to be resolved to guarantee the success of the idea:\(^{(45)}\)

- importance of a proper theoretical modeling of the sensor chips
- availability of microfabrication technologies suitable for realizing sensors based on a variety of substrate materials, such as glasses, polymers and semiconductors
- fluidic interfacing of the MEMS parts is probably the most critical issue to be solved when going to production and often can make or break a project
- possibility of mass-producing low-cost chips.

In the following we will limit our discussion to the applications of MEMS that apply to the analysis of gases and vapors using gas sensors and gas chromatography.

### 5.1 Gas Sensors

The detection of gases with chemical sensors based on MEMS technology is a very dynamic market. According to a recent market survey published by Frost & Sullivan\(^{(46)}\), the industrial gas sensor market for the USA was $329 million in 1992, advancing to $427 million in 1994. It was expected that the steady growth should continue, propelling the market size to $1.03 billion in 2000. The compound annual growth rate for the period 1994 to 2000 is forecast to be 15.9%. These estimates and forecasts apply to the basic devices offered by manufacturers of gas sensors and often include a limited amount of integral electronics included in the sensor package.

The European industrial gas sensors market increased from $141.7 million in revenue in 1994 to $154.3 million in 1997. Growth of both unit shipments and revenues were witnessed over this time following the economic improvements in Europe and advancements in the manufacturing and performance of gas sensors. Continued growth of the market is expected in the forthcoming years supported by low, but increasing prices and increasing applications. Frost & Sullivan expects the total European industrial gas sensors market to increase to $221.0 million in 2004, from almost 3 million units shipped. The main source of new applications for gas sensors is expected to be new European legislation governing some industries. There will be several other factors driving the market in the coming years.

One factor contributing to the worldwide growth is the continuing increase in government regulations concerning personal safety, confined spaces in the workplace, continuous emissions, ambient air, and the environment. Even where government regulations do not apply, public awareness about these considerations is increasing.

Other factors have played, and will continue to play, an important part in driving the gas sensor market. Advances in technology, together with competition among the various approaches to gas sensing, have provided a hospitable environment for increasing use of sensors. Since more than one approach is available to detect many industrial gases, competition among these approaches forces manufacturers to enhance the performance of their products. The lack of selectivity of solid state sensors, in general, is making for a very fast growing market for the more selective but more expensive wet electrochemical gas sensors and the newly emerging inexpensive optochemical techniques,\(^{(47)}\) but the subject is out of the scope of this article about MEMS.

A family of sensors based on surface loading which are attractive for environmental measurements are the surface acoustic wave sensors (SAWs). SAWs are MEMS structures which have been under intense investigation during the 1990s as a basis for chemical gas sensors. These are resonators, reflective delay lines, and dispersive structures containing two interdigitated transducers coated with a polymer film (Figure 7). Application of an alternating voltage to the input transducer generates a strain field in the underlying quartz caused by its piezoelectric properties. The strain field launches a surface acoustic wave that travels along the substrate, interacting with the overlayer film, before being converted back into an

---

**Figure 7** Schematic view of a SAW. Two interdigitated transducers are on the top of quartz substrate and are coated with an absorptive polymer film. The signal transmission is delayed by the adsorption of gas molecules on the surface and the corresponding signal is proportional to the concentration of the gas.\(^{(48)}\)
MEMS TECHNOLOGY APPLIED TO MINIATURIZATION OF FIELD INSTRUMENTATION

---

**Figure 8** Schematic diagram of a MOS transistor used for the detection of volatile organic vapors. The presence of volatile organic compounds (VOCs) change the characteristics of the transistor. \( V_g \) is the gate voltage, \( V_d \) is the applied junction bias, \( w \) is the width and \( l \) is the length of the channel.

Electrical signal by the output transducer. The wave/film chemical or physical interaction with the molecules of gas to be detected results in a perturbation of the wave propagation properties, specifically the wave velocity, \( v \) and the wave attenuation \( a \) (the rate of wave diminution with the distance). This sensitivity to thin film properties makes SAW devices well suited for chemical sensors to monitor gas and vapor species with a typical sensitivity of a few parts per million.

SAWs are also sensitive to a broad range of perturbations in addition to surface mass loading. Changes in the electrical, mechanical, or rheological properties of a thin film or other medium in contact with the device surface can induce a response. Extrinsic variables such as temperature, pressure, and electric field can perturb SAWs as well. Such multiparameter sensitivity is a double-edged sword, while providing a multitude of physical mechanisms to probe interfacial chemical interactions, it also creates responses to unintended perturbations, with confusing or misleading results.

SAW chemical sensors offer considerable promise for the future, particularly for those applications where their sensitivity to surface mass changes, or the ability to provide two-dimensional (velocity and attenuation) responses to multiple perturbations, offers a competitive edge that outweighs the costs of making measurements at radiofrequencies. SAW radio sensors make it possible to read measurement values from a remote location\(^{(49)}\) using a radio emitter. The decisive advantage of these SAW sensors lies in their passive operation with simple radiofrequency electronics, and in the possibility of wireless installation at particularly inaccessible locations. Despite a fairly good understanding of the fundamentals of SAW chemical sensors, they have yet to be widely applied to commercial problems.\(^{(50)}\)

A sensor for the detection of gases needs to be able to produce an electrical response which is dependent on the concentration of gaseous species present. One type of detector which satisfies this criterion and is also capable of being integrated into the associated electronics is the gas-sensitive metal oxide semiconductor (MOS) transistor. This transistor is a device in which the conduction between the source and drain is modified by a charge or potential on the gate electrode (Figure 8). Basically, the device is a capacitor with one electrode being the gate and the other the channel. The conduction of the channel is controlled by the charge present on the gate. Hence anything which alters either the potential of the gate or the charge at the gate will alter the conduction of the channel and this change can be detected as an electrical signal which can then be processed. Gases absorbed or adsorbed onto the gate change either the potential or the charge on the gate. This can occur by a number of different mechanisms. Either the gas can chemically interact with the gate material and change the Fermi energy, or else the gas can induce dipoles in the gate which will alter the potential gradients at the gate–oxide interface, or else a chemical cell can be formed between the gate and the oxide. All these mechanisms will alter the potential or barrier height at the gate–insulator interface and hence modify the channel conduction.

Catalysis gas sensors form another type of semiconductor used for vapor and gas detection. They are characterized by reduced power consumption as low as 100 mW, and are well suited to portable gas detection devices. Sensors with a base material of tin dioxide and 4 wt % of Pd dopant are fabricated by means of thick film technology. Both the composition parameters.
of the sensing layer and the heater are optimized in order to sense propane/butane in air with the threshold level of 100 ppm. The original method of tin dioxide preparation for the sensing layer and for the thick film heater being stable at temperatures up to 600 °C has been demonstrated.\(^{51}\)

Cyrano Sciences Inc. (Pasadena, CA) is developing an array sensor called “electronic” nose to be released late 1999. The hand-held system is lightweight, hand portable and operates on batteries (Figure 9).

The sensing mechanism is based on the use of a carbon loaded polymer that expands like sponge when it comes in contact with a vapor, increasing the resistance of the composite. An array of 32 channels with different responses produces a distinct response signature. This unique response results in an electrical fingerprint that is used to characterize any odor. The typical response time of the array is 10 s.

Figure 9 Portable “electronic nose” for use in the field to detect volatile compounds. The device incorporates a LCD (liquid crystal display) and a flexible sniffing tube. Rapid response time provides an effective and accurate measure of vapors present. (Reproduced by courtesy of Cyrano Sciences, Inc.)

5.2 Portable Gas Chromatographs

The conventional approach to off-site gas analysis measurement relies on the collection of the samples in the field and measurements in the laboratory. Despite its apparent simplicity, this approach presents numerous drawbacks. The process of collecting a gas sample in a vessel and transporting it to the laboratory for analysis delays the results and quite often causes the sample to degrade, making the analysis inaccurate or not representative of the mixture from which the sample had been taken. Portable instrumentation, on the other hand, allows on-site measurements directly at the sampling source and thus provides limited risk of sample degradation, better accuracy, potentially greater sample throughput and almost immediate results more economically than with traditional technology.

What is the analytical price to pay in order to gain portability? Many conventional analytical instruments operate at or near their theoretical limits and, before reducing the size of the instrument, it is necessary to understand the effects of the “scaling factor” on the performance of the instrument. For instance, if the speed of a GC analysis is to be reduced from minutes to seconds, the internal volume of the detector must be scaled down proportionally, but the sensitivity can suffer. The next question regarding size reduction is the access to the right technology, but research in instrument miniaturization has demonstrated that the development of portable GCs based on MEMS is possible. This interrelationship of MEMS components is what led to the “GC-on-a-chip” designed in the late 1970s/early 1980s at Stanford University\(^{1,2}\) and its spin-off the P-200 GC developed by Microsensor Technology Inc. (MTI) now commercialized by Hewlett-Packard (Figure 10).

The GC-on-a-chip, as it was then called, was constructed on a 2\(^{\circ}\)-(5 cm) wafer with a miniature sample injector, a microcolumn and a microthermal conductivity detector (MTCD). Micrometer-dimensioned features were created by using IC process techniques such as photolithography to pattern, and chemical etching technologies to create precision shaped structures. These 3-D structures were then bonded into place and connected to several other microstructures to form at that time the world’s smallest and fastest GC. The sample injector incorporated a 10-µm wide sample loop and injected the sample composition onto a 1.5-m long capillary column, wound into a shallow groove of approximately 200-µm wide and 40-µm deep coated with a thin film of liquid phase. The column was wound into a spiral to enable its placement on the wafer. Once separated, the sample elements were analyzed by a microfabricated TCD.\(^{52}\) The chip was fabricated on a separate wafer and the thin-film sensor deposited on the top of a thin layer of sputtered...
Pyrex®. The chip was mechanically clamped on the end of the column. The interface between the sample injector, the GC column and the dual-detector cavity were all silicon micromachined. A Pyrex® cover plate, electrostatically bonded to the silicon substrate, ensured that the GC structure was leakproof. The GC-on-a-chip could separate a simple gas mixture composed of nitrogen, pentane, and hexane in less than 5 s.\(^2\)

Before microbore fused-silica capillary columns first entered the market, the Stanford team made an attempt to etch the column directly on a silicon wafer. These micromachined GC devices were the only available components that could provide fast analysis. High-speed chemical separations (analyses requiring less than 120 s) were eventually realized with the interfacing of silicon micromachined components and later with commercially available quartz microbore capillary columns. By the early 1990s, refinements were made to improve manufacturability and reduce costs and MTI began to produce both portable and laboratory Micro GC instruments.

The principal market for these small high-speed instruments was for the analysis of ambient VOCs. Analysis times were typically 60 s or less depending on the composition being analyzed. These instruments were focused on three major markets: (1) chemical/petrochemical, (2) natural gas and (3) fixed gases. Using the same modular construction, the Micro GC could be configured to have up to four (Quad) GC modules in a single instrument. Since each module had its own injector, heated microbore column, and TCD, the instrument could perform up to four separate but parallel analyses, permitting complete analysis of complex compositions in an extremely short period of time.

This portable GC combines the varied aspects of silicon micromachining and conventional technologies to fabricate a gas injector and a TCD.\(^5\)(The gas injector for instance is a hybrid approach of micromachining technology and conventional machining,\(^4\)) and provides a sharp plug injection function necessary to avoid peak broadening with small bore columns.

Figure 11 shows quantitative results of a comparison between the Quad series refinery gas analyzer (RGA) and a conventional laboratory instrument. The test was done by measuring the relative standard deviation of the retention times for the various components of a refinery gas sample. The standard deviation for each of the peaks is smaller for the portable instrument than for the conventional GC and shows that miniaturization does not affect the performance of the portable instrument.

A typical Micro GC instrument incorporates up to four GC modules. Each module consists of a silicon micromachined gas injection system (Micro Injector), a four filament silicon micromachined TCD (Micro TCD), and a heated microbore capillary column connecting the injector to the detector. These devices are encapsulated between two pieces of thermal insulating foam and packaged in a 4 \times 4 \times 6 inch (100 \times 100 \times 150 mm) metal enclosure. In addition to the modules, the instrument also contains a vacuum pump and a pressure-regulating manifold for each module. The portable series also includes a 0.3-L carrier gas cylinder and a 12-V dc battery power system for field use.

Figure 12 is an open view of the MTI-P series Portable GC showing all the elements of the GC. The sample inlet, at the front of the instrument, is heated to 110°C to prevent water condensation. A gaseous sample is introduced to the instrument through the sample inlet port(s) using the built-in vacuum pump and is distributed through the separate GC modules simultaneously.

### 5.2.1 Micro Injector

The Micro Injector is constructed of four laminated layers of materials which form a single unified functional component that measures approximately \(1 \times 1\frac{1}{8} \times \frac{3}{4}\) inch (25 \times 30 \times 3 mm) thick. Part of the injector assembly (Figure 13) controls the microfluidic movement of the...
Figure 11  Bar graph showing the relative standard deviation of retention times measured on a conventional GC (in gray) and on the Micro-GC, P-200 series (in black), for a standard mixture of components of a plant stream. The increased speed of the analysis performed by P-200 Micro-GC does not show any degradation of the results. (Reproduced by courtesy of Hewlett-Packard Company.)

Figure 12  Open view of the portable dual micro GC developed by MTI. The illustration shows a P-200 GC with two GC modules in the lower right corner of the instrument. The GC modules contain an injector, a heated capillary microbore column and a MTCD encapsulated in high-temperature insulation. (Reproduced by courtesy of Hewlett-Packard Company.)

Figure 13  The Micro Injector precisely controls the fluidic movement of carrier and sample gas throughout the Micro GC. The 32-µL serpentine sample loop supplies the column with preselected sample volume of 1–10µL for separation. The body of the Injector consists of two Pyrex® layers, a Kapton layer and an etched silicon layer sandwiched together as a unit. (Reproduced by courtesy of Hewlett-Packard Company.)

gases throughout the complete analytical process. While in the standby mode, the injector receives and stores
the sample gas in its serpentine sample loop. With precise micromachined valves, it injects a predetermined amount of sample gas into the carrier gas stream of the GC. The MEMS etched silicon layer of the injector includes normally open and normally closed valves, a flow restrictor channel, and several sizes of gas channels linking the various mentioned devices together. The injected quantity of gaseous sample is variable up to 31 $\mu$L.

This MEMS design of the injector has several distinct benefits:

- small sample paths introducing little band broadening
- high speed of operation necessary for fast analysis
- four valves integrated in the injector that can be operated independently.

The flow-through sample valve is shown in Figure 14 whereby the sample gas enters the valve body from one of the outer ports, flows around the sealed center port, and exits the opposite outer port to vent. When the diaphragm lifts, opening the center port, the sample gas is pushed through the center port and onto the column for separation. Precise opening time and constant inlet pressure enable the GC to repeat accurate sample injections every time.

The normally open/normally closed valves are of the same construction except there is only one outer port and the center port is either normally opened or closed. A separate pilot solenoid valve pneumatically pressurizes the upper half of the diaphragm, forcing it down onto the valve seat and sealing the gas flow. The diameter of the valve body is 2500 $\mu$m with a 300 $\mu$m valve seat for a total dead volume of less than 10 nL. Opening and closing of the valve occurs in less than 5 ms with the 15-\(\mu\)m movement of the diaphragm. With this type of precise control, these microvalves can introduce accurate amounts of sample gas onto the column with extremely high levels of repeatability and accuracy. The length of time the valve stays open determines the precise amount of sample volume that is pushed onto the column for gas separation. The valves can be operated above 100°C for millions of cycles without any signs of wear or fatigue.

Valves are an important part of MEMS used for the control of fluids in analytical instruments and the hybrid approach chosen for the valve here is specific to the design of this instrument. There are several other micromachined valve designs besides pneumatic driven valves using separate solenoid pilot valves. Some combine the valve actuator with the microvalve design based on a variety of principles including electrostatic force,54 liquid expansion,55 bimetallic expansion,56 thermal expansion57 and, for liquid control applications, piezoelectric actuation.58 An interesting application of MEMS components applied to gas control is a proportional microvalve developed by Hewlett-Packard Laboratories.59 This valve is thermally actuated by a metallic actuator and is totally integrated, meaning that the actuator and the body of the valve are part of the same assembly. This mode of actuation precludes operations at elevated temperatures, but offers the advantage of proportional flow control of gases starting as low as a fraction of a microliter per minute up to liters per minute at pressure up to 200 psi (1.3 x 10^6 Nm\(^{-2}\)).60

5.2.2 Microthermal Conductivity Detector (MicroTCD)

The MicroTCD used in the HP Micro GC is another example showing that MEMS technology is very well adapted to solve analytical problems. Small-bore columns are used to perform fast analyses, but when the internal diameter (ID) of the column decreases, peak width increases when all other instrumental parameters are unchanged. To avoid broadening peaks in the chromatogram, the internal volume of the detector should be of the same order as the ID of the column. MEMS technology is particularly well adapted to solve this type of problem and gives the designer the ability to fabricate 3-D structures with small internal volumes. The MicroTCD, for instance, has an internal volume of 180 nL, which is perfect for microbore columns. Higher sensitivity is an inherent characteristic of concentration in microdetectors.
over mass detectors when the internal volume is decreased. Van Es from the University of Eindhoven, for instance, has shown that the sensitivity of the MTCD for n-C7 becomes comparable to the flame ionization detector when columns of 100 µm or less ID are used.  

The MicroTCD is shown in Figure 15. It has two parallel pneumatic channels (reference and detection) running through the center of the silicon die, with two nickel filaments suspended over each channel. The four 0.8-µm thick nickel filaments are electrically connected to form a Wheatstone bridge resistor circuit. These filaments are the sensing portion of the detector and because of their small thermal inertia can be sampled 100 times per second. These nickel filaments are suspended across a 250-µm wide by 50-µm deep trapezoid-shaped channel and are located in the center of each channel that was formed during the anisotropic etching part of the micromachining process. The other half of the two channels is machined into the Pyrex® cover plate, aligned and anodically bonded to the silicon detector die. The anodic bond seals the two parts together, completing the formation of both channels with two filaments suspended in the middle of each channel.

A magnified view of a detector filament cross-section is shown in Figure 16. The filament suspended above the silicon channel is entirely supported by a silicon dioxide membrane. This filament is made of an evaporated 0.8 µm thick nickel layer, sealed with a thin film of silicon nitride for corrosion protection. The thermal conductivity changes in the environment are detected by measuring the changes in current being applied to the filaments in order to maintain a constant filament temperature. The higher the difference in thermal conductivity, the greater the signal.

5.2.3 Microbore Capillary Column

A major trend of GC has been to reduce analysis times by using small bore columns to provide near-real-time monitoring. Separation times in high-speed gas chromatography (HSGC) are in the range of seconds rather than minutes and such speed can only be achieved by using small bore columns and limiting peak broadening. Practical limits for fast analysis using currently available instrumentation are understood. Some of the working solutions consist of getting a sharp sample introduction plug inside the instrument, programming the column temperature at high rates and reducing internal dead volumes. The early attempt by the Stanford team to use a MEMS approach to integrate an injector, a column and a detector to a silicon wafer was an excellent approach to eliminating the causes of peak broadening due to the interconnection of the components, and at the same time produced etched channels of small dimensions to provide fast separation. They were successful in reducing internal volumes, but overall provided a GC system with poor analytical performance. The main reason is that the cross-section of an etched column is far from being circular (actually,
it is closer to being a semicircle when the channel is isotropically etched) and therefore the thickness of the liquid film inside the column is not constant, thus creating a broadening of the peaks and resulting in a low column efficiency. For practical reasons, the length of a column that can be etched in a silicon wafer can hardly exceed a few centimeters and therefore limits the analytical separation to only a very simple analysis. For these reasons, it was decided to abandon the etched column and choose conventional small bore capillary columns.

Several papers in the literature discuss the use of narrow-bore wall coated open tubular (WCOT) columns for high-speed capillary GC. The main conclusion is that the ID of the column should be reduced to at least 0.32 mm but not less than 0.1 mm to achieve a fast analysis without significant loss of resolution. The most serious problems to overcome to reduce even further the ID of the column below 0.1 mm are the difficulty in dealing with the limited sample capacity of the column and with the practical reduction of the internal pneumatic volumes in series with the GC system.

A typical microbore capillary column used in Micro-GC is shown in Figure 17. These columns are made of quartz glass, have ID tubing between 0.1 mm and 0.53 mm, up to 50 m long. The exterior is coated with a thin film of polymeric polyimide to protect the glass tube from fracturing. The internal wall of the tube is coated with a thin layer of polar and nonpolar material or solid adsorbent formulated to separate specific gases as they flow through the column.

5.2.4 Field Applications of a Portable Gas Chromatograph, Micro Gas Chromatograph from Hewlett-Packard

The P series Micro GC from Hewlett-Packard is an illustration of how MEMS technology can elegantly solve some old analytical problems.

5.2.4.1 Natural Gas Analysis A typical natural gas analysis performed off-site consists of collecting the sample and bringing it to a laboratory to be analyzed for the British thermal unit (BTU) value by volume. This is slow, time-consuming and very often inaccurate. The Micro GC ensures accurate and rapid data analysis directly at the well head site. The overall analysis is done directly in the field with an accuracy of ±2% relative standard deviation ±1 BTU in 1000.

The Micro GC also performs extended analysis of natural gas samples. Extended analysis is the separation of natural gas without the grouping of C6+ (hexane and beyond). The BTU content of a sample is calculated from the individual BTU values of C6(hexane), C7(heptane), C8 (octane) and C9 (nonane), instead of using an average C6+ value (hexane, heptane and octane). This analysis generally takes 35 min with a conventional GC but is performed in less than 140 s with the P-200 series Micro GC.

The results of the analysis with a P-200 equipped with two analytical modules are shown on Figure 18. The first module contains an OV-1 (8 m × 0.15-mm ID) micropacked column for baseline separation of nitrogen, methane, carbon dioxide, ethane and propane. The complete separation of these samples is done in less than 80 s (Figure 18). The second module contains a PLOT U (8 m × 0.320-mm ID) capillary column to separate isobutane and normal butane, isopentane and normal pentane, hexane, heptane, and octane. The analysis of these components is done in less than 130 s.

5.2.4.2 Analysis of Landfill Gas Landfill gas generates unpleasant odors, greenhouse gases and VOCs as well as by-products, which can cause explosions and fires, and kill vegetation. Consequently, regulatory agencies are imposing increasingly stringent requirements on the amount of landfill gas that can be released into the environment, often requiring collection systems (wells) to be installed.

A landfill gas analyzer separates and analyzes H2, CO, C1 (CH4-methane), O2 and measures the anaerobic efficiency of the bacteria in the landfill. Two modules are used for this determination. The analysis of the permanent gases H2, O2, N2, CO and CH4 is done in less than 45 s using a 10 m, 0.32-mm ID, 30 µm dl, microbore molecular sieve 5A PLOT column (Figure 19a, Channel A). The fixed gases and light hydrocarbons are separated using a 4 m, 0.32-mm ID PorapLOT-U, 10 µm dl column to
Figure 18 Field application of the P-200 GC analyzing 1100 BTU natural gas. Channel A of the instrument is equipped with an OV-1 column and separates C1 through C3 in 80 s (a). Channel B is using a PLOT U column and separates components from C4 through C8 in 130 s (b). The operator performing the separation in the field is shown in (c). (Reproduced by courtesy of Hewlett-Packard Company.)
LANDFILL GAS ANALYSIS

Figure 19 Landfill gas analysis is used to measure the anaerobic oxidation efficiency in nature’s decomposition process. The P-200 GC is equipped with two GC modules (Channel A and Channel B). Channel A monitors the oxygen and nitrogen using a 4 m × 0.32 mm ID molecular sieve column for separation at 50 °C (a). Channel B separates air, carbon dioxide and methane on a 0.25 m × 0.5 mm ID HayeSep A Micropack column at 40 °C (b). The actual measurement with this portable instrument is shown in (c). (Reproduced by courtesy of Hewlett-Packard Company.)

When using or selling gas as an energy source, the operator can calculate the BTU content to determine pricing. BTU information is also valuable for deciding where to place new landfill wells and when to start harvesting gases, e.g., the methanogenic state of the landfill.

5.2.4.3 Refinery Gas Analysis

The petrochemical industry uses the Micro Quad series GC (which houses up to four independent column modules) to perform an analysis of a complex mixture of refinery gases, called refinery gas analysis (RGA). Configured with dual carrier gas inlets (helium and argon), the sample is pulled into the instrument and simultaneously distributed to each of the four Micro GC modules and analyzed in less than 3 min. Each of these modules is independently temperature and pressure controlled, and has a precolumn to protect the analytical columns and reduce analysis time.

The first column module (Figure 20a, Channel A) consists of a 0.32-mm ID 10-m molecular sieve 5A PLOT, operating at 110 °C, which uses argon as its carrier gas and has a 0.7-m PorapLOT-U precolumn for backflush-to-vent. Channel A specifically analyzes H₂, O₂, N₂, CH₄ (methane), and CO in 130 s.

The second column module (Figure 20b, Channel B) consists of a 0.32-mm ID, 8-m PorapLOT-U operating at 80 °C that uses helium as a carrier gas and uses a 1.0-m PorapLOT-Q precolumn for backflush-to-vent. Channel B specifically analyzes methane, CO₂, ethylene, ethane, acetylene, hydrogen sulfide, propane/propane, propyne and C₄ plus (butane) in 100 s.

The third column module (Figure 20c, Channel C) has a 0.32-mm ID 10-m Al₂O₃ column and uses helium as a carrier gas. Channel C separates propane, propylene, C₄n-butane and isobutylene, and C₅ pentane hydrocarbons in 130 s.

The fourth column module (Figure 20d, Channel D) uses a 0.15-mm ID 10-m OV-1 column and uses helium as a carrier gas with backflush-to-vent. The OV-1 analyzes C₄ isobutene through C₆ normal hexane in 85 s.

These examples show that there are values associated with the implementation of miniaturized components. Smaller components increase speed to analysis and reduce the volume of carrier gas needed. Less sample gas is also needed to obtain the same result, but faster. Reduction in component size enables the instrument to be smaller and occupy less costly bench space. When smaller and lighter components are available enabling lightweight portable instruments to be designed, these instruments can be easily carried into the field to perform on-site analysis. Speed of analysis enables the user to acquire and analyze more samples in a given time period, saving money and increasing the amount of available data. The disadvantage of miniaturization is lack of the versatility found in laboratory instruments. Portable
instruments have to be specialized for use in a few specific applications.

5.3 Miniaturization of Mass Spectrometers

Finally, we should also mention briefly the work done in the miniaturization of MSs. Mass spectrometry, when combined with GC, continues to be a standard method for the identification and characterization of gaseous chemical species. It is widely used in environmental, medical, military, and industrial applications, and would see even broader use if the equipment were truly portable for field measurements. To date, most of the equipment used for high-performance MS is based on conventional technology and is adapted to laboratory measurements.

There have been a few attempts to apply MEMS technology to portable MS and we will report preliminary results available for two of them. The Applied Physics Laboratory has developed a small, powerful, time-of-flight MS in a collaborative program with the Johns Hopkins Medical Institution and the University of Maryland. Miniaturization of the equipment required the development of new techniques for ion formation in the ion source region and the use of kinetic-energy spread correction schemes based on ion reflectrons. Sampling and ionization schemes for solids, liquids, and vapors have led to promising conceptual designs for microorganism identification, environmental monitoring, and law enforcement analytical tools.\(^{68}\)

The Jet Propulsion Laboratory (JPL) has initiated a program to miniaturize and ruggedize a quadrupole mass filter using MEMS techniques to make them suitable for space missions.\(^{69}\) The JPL program objective is to

---

**Figure 20** The refinery gas analysis utilizes four independent Micro GC modules to analyze simultaneously a complex gas sample in less than 160 s. The same analysis performed with a conventional GC instrument would take from 30 to 60 min. (Reproduced by courtesy of Hewlett-Packard Company.)
achieve a mass range of 1 to 300 atomic mass units (amu) with a resolution of 0.5 amu. This compares favorably with the 15–212 amu range and a 1-amu resolution of the MS used on the Viking I and II spacecraft, which landed on Mars in 1976. The LIGA technique will be used to create quadrupole rods 2.2 mm in length. To achieve the stated dynamic range and resolution, pole dimensions must be controlled to within 0.1%. Although this geometrical accuracy is yet to be demonstrated, it is within the theoretical limit of the LIGA technique.

6 CONCLUSION

The microsystems industry is now a rapidly growing sector of MEMS that has emerged since the late 1960s. The onset was mainly a technological spin-off from microelectronics/IC technology. Silicon micromachining gave the main triggering technology push as a very promising process technology with distinctive features. Sensor applications gave the first market opportunities and batch-organized processing technology adapted from the microelectronics industry provided the key to high quality at low cost. Today, MEMS has matured into a separate industry sector with its own market and manufacturing infrastructure with a use of materials other than silicon. Microsystems based on MEMS are used for applications ranging from low-cost, high-volume automotive applications to high-cost, low-volume instrumentation applications for the aerospace industry. Sensors used by the automotive industry continue to be the prime market for this technology and are used more and more to reduce production costs and provide more sophisticated and reliable instruments.

In this review of applications to chemical instrumentation we have shown how MEMS technology has been used to produce components which have a unique performance. There are now enough documented applications to indicate that this technology is real and will eventually change the industry. We have described how MEMS technology has been applied to produce components of small internal sizes and thus improve the performance of the instrument.

1 INTRODUCTION

The first incentive to operate mobile mass spectrometers came from space research to investigate the gas and surface material of Venus (Pioneer program)\(^1,2\) and Mars (Viking Mars mission\(^3,4\)) in the early 1970s. Also in research on the atmosphere of the earth, mobile MS experiments (e.g. on balloons and in rockets) were accomplished.\(^5,6\) For vapor sniffing a small three-stage membrane quadrupole mass spectrometer has been constructed to detect explosives, chemical effluents and drugs.\(^7\) In addition to this research equipment, military applications and instruments for detecting chemical warfare agents on the battlefield have been developed, and several hundred of these specially designed systems are installed in reconnaissance vehicles.

The requirement to detect chemical substances in the field safely almost inevitably led to the measurement principle of MS. If organic compounds are to be detected, a large variety of substances with different molecule sizes and functionality have to be taken into account. Suitable detectors must be able to supply a multiplicity of detailed item information. Apart from mass spectrometers, basically, infrared (IR) spectroscopy performs this task well since it achieves an extremely high degree of interaction with the analyte. However, only structures of molecules which reach a state of resonance with electromagnetic radiation can be detected. Accordingly, only fractions of the molecule are described. If there is a restriction with regard to evaporable materials, MS is the most successful chosen detection procedure. All basic modules of the molecule structure are taken into account. The molecular ion determines the molecular weight of the material, and fragments, which usually consist of characteristic parts of the molecule, permit identification of the substance simply from the typical fragment patterns. Furthermore, the sensitivity of current mobile mass spectrometers is superior to that of commercial mobile IR instruments. For mixtures, chromatographic separation prior to MS detection facilitates identification and quantification. This is usually achieved by coupling gas chromatography (GC)
with MS (GC/MS). Identification is carried out by spectrum comparison with commercially available spectrum databases.\textsuperscript{8,9}

As a result of the military developments, progress in microelectronics and miniaturization of laboratory MS devices, mobile MS systems are now also available in the civil sector. They are used for analyzing contaminated air, soil, water and waste, in worker protection as well as in chemical accidents.

The use of mobile instrumentation, in particular mobile mass spectrometers, for environmental measurements offers many clear advantages compared with analysis performed in stationary laboratories. The main advantages are

- sample handling and transportation steps are minimized when the analysis is performed on-site/in situ;
- possibilities of the change of sample composition are minimized since samples are analyzed in real-time or near-real-time;
- rapid and reliable identification and quantification capability in various types of emergency situations (e.g. fires, chemical spills);
- unexpected or unusual analytical results can be confirmed rapidly;
- reduced total analytical costs during remediation of a contaminated site.\textsuperscript{10–12}

This article therefore aims to present the current level of development of the MS or GC/MS technique with mobile devices and their efficiency as an example of the overall possible and necessary improvement in analytical techniques.

2 INSTRUMENTATION\textsuperscript{10,13–19}

In the mass spectrometer ions are separated in electrical and/or magnetic fields and their masses are measured (Figure 1). Common devices ionize the molecules by electron impact. Emitted from a glow cathode, the electrons are accelerated to 70 eV. The mass separation process takes place in a vacuum chamber evacuated to at least 0.01 Pa ($10^{-7}$ bar) to allow a collision-free flight path through the analyzer.

Frequently used inlet systems implemented in mobile devices and mass separation processes are described below. Since signal overlay by the presence of many compounds in a mixture prevent identification and quantification, gas chromatographic columns are used in some devices. Their mode of operation is also briefly described.

The description of the operating principles of the machine is limited to constructions that are actually used in mobile devices or would possibly be suitable.

2.1 Inlet Systems

The function of the inlet system is to transfer gaseous substances into the vacuum section of the device according to the efficiency of the vacuum pumps. The easiest method of implementation is by means of direct inlet systems using defined leaks formed by a thin hole or a capillary, inlets using differential pumping (Figure 2a) (e.g. jet separator) or by means of the membrane separator (Figure 2b).\textsuperscript{17,20,21} Since direct inlets are more easily contaminated upon entry of non-volatile materials or particles than those which use a membrane, they are normally only used for gas analysis or coupled with GC. In differential inlets high-volume sample transfer through the inlet line is achieved. The risk of contamination compared with restriction capillary inlets is smaller owing to the short contact time of the sample to inlet parts.

In the membrane separator the sample gas is sucked through a thin silicone tube leading through the vacuum whereby a fraction of the gas passes through the silicone membrane into the vacuum by permeation.
processes. In addition, flat membrane layers are used. Owing to the hydrophobic nature of silicone, organic components are introduced into the vacuum while polar compounds (mainly water) are discriminated. Also semi-volatile materials (up to benzopyrene or polychlorinated biphenyls (PCBs)) can be analyzed whilst heating the membrane. The advantage of membrane separators is their extremely good durability. However, they may only be used for volatile compounds if they are not heated. If they are heated this involves higher machine expenditure and high levels of energy consumption.

2.2 Mass Separation

During mass isolation we basically distinguish between two procedures: separation in time (SIT) and separation in space (SIS). In the case of SIT the separation system works like a variable filter which allows different masses to pass temporally. The quadrupole\(^{(18)}\) (Figure 3) and ion trap systems\(^{(22,23)}\) (Figure 4) are examples of this method. The advantage of SIT separation systems is their compactness. The ion trap arrangement offers the additional possibility of holding individual ions and letting them fragment again in the mass spectrometry/mass spectrometry (MS/MS) mode.\(^{(24)}\) Nonscanning magnet sector field devices with detector array\(^{(25)}\) (Figure 5) and time of flight (TOF) mass spectrometers\(^{(26)}\) (Figure 6) are examples of SIS. In a magnetic mass spectrometer the moving energy of the accelerated ion cloud is focused by an electrostatic field and the masses are separated in the magnetic field on discrete ion flight paths to be finally measured by a set of detectors. In the TOF mass spectrometer after acceleration, the ions are separated according to their mass-related different TOF. The advantage of these devices is that they are very fast (full spectra within a few milliseconds for SIS compared with a few 100 ms for SIT).

2.3 Mixture Separation by Gas Chromatography\(^{(27)}\)

The gas chromatograph consists of an injector in which the sample is sucked in or evaporated, and a capillary (inner diameter 0.1 to 0.5 mm) through which the carrier gas passes, moving the compounds through the column while separation takes place. A part of the sample is injected into the gas flow and conducted through the capillary. Interaction with a polymer coating on the inner wall of the capillary causes the compounds to separate. Analytes may be volatile organic compounds (VOCs) as well as semivolatile organic compounds (SVOCs). They are isolated according to their different evaporating ability and within certain limits remain briefly or longer according to their different polarity in the polymer. This makes it possible to separate even complex mixtures. Heating the capillary results in faster movement of the compounds through the column. Thus, at high temperatures the run times of semi-volatile compounds may be substantially shortened. However, separation under a constant temperature (isothermal operation) takes place within compound groups of a small range of evaporating ability. More volatile compounds pass unseparated ahead and low-volatiles remain on the injector side. Increasing the temperature continuously (temperature-programmed GC) causes all
injected substances to pass through the capillary with optimal separation power at any range of volatility. Regarding mobile applications it is important to mention that temperature programming requires a much higher amount of power than isothermal heating.

Generally, injection temperatures range from 200–300 °C. Similar temperatures are possible as a maximum for heating the separation film on the inner surface of the capillary. Usually nitrogen or helium is used in mobile devices as the carrier gas. In addition, the use of carbon dioxide may have certain advantages. Since modern GC phases have become extremely stable towards high temperatures and chemical reactions as a result of polymer cross-linking and covalent linkage to the capillary wall (chemical bonding), air can also be used as a carrier gas without degradation of the phase at high temperatures. Filtered ambient air is generally used in such applications.

The duration of the chromatographic run depends on the slope of the temperature program and the length of the separation capillary. Lengths between less than 1 m and 15 m are the norm in mobile gas chromatographs. Separation in very short capillaries is called transfer-line chromatography because the restrictor transfer line to the MS is used for sample gas feed and fast separation in one. The run times in transfer-line GC vary between seconds and some minutes. Especially for fast GC/MS, where co-elution of compounds with similar volatility frequently occurs, evaluation procedures are available to deconvolute even strongly overlapping signals. Thus, spectra from clean compounds are generated and used for clear identification based on MS database comparisons. Fast GC/MS analysis of PCB mixtures has proven that from GC runs of 5 min the information of separations that usually last 40 min may be extracted.

Procedures allowing on-line chromatography without injection by impressing a modulation signal at the injector side of the capillary, is briefly mentioned here. This technique seems to fit in very well with the demands on fast on-line measurements. For example, it is supposed to be a future alternative to conventional GC in chemical analysis on board spacecraft.

3 SAMPLING

Sampling techniques with a low level of instrument expenditure and sample preparation, which are feasible in the field, are described. The summary is subdivided into applications for the on-line measuring technique and the procedures suitable for the different matrices occurring in the environment.

3.1 Gaseous Samples

For gas sampling plastic foil bags made of inert material (Tedlar®) are used. High-grade steel cans with a passivated surface against adsorption and glass vials are also used. They are evacuated before measurement and the sample is gathered locally by opening a valve. Usually subsets are transferred into the analyzer with gas-tight glass syringes.

Sampling with simultaneous enrichment is performed by enrichment on an adsorbent. Tenax® is the most commonly used material since humidity from the air is not enriched and therefore does not adversely affect the thermal desorption and injection. If extremely volatile materials, such as vinyl chloride which barely adsorbs on Tenax®, are to be enriched, traps with different adsorbents are used, e.g. a Tenax™ packing is followed
by modified activated charcoal layers with a higher surface activity.

Gaseous samples can also be analyzed directly without a separate sampling step by introducing the gaseous sample into the ion source of a mass spectrometer via a direct inlet, such as valves or capillaries, or via a membrane inlet. These methods offer an excellent means for on-line monitoring of gaseous streams or ambient air as well as industrial emissions.

3.2 Water Samples

Of the different sampling procedures for water, sampling with amber-colored bottles is the most usual method used. This original sample is filled without headspace and properly sealed to reduce the risk of loss of highly volatile compounds during transport.

For headspace analysis this sample is filled into another gas-tight vial with a defined headspace, where the volatile substances are in equilibrium with the liquid phase. The compounds are taken either directly out of the gas space from the bottle using a gas-tight syringe for direct injection or enriched by adsorption to an adsorptive layer inserted into the headspace (commonly known as solid-phase micro extraction, (SPME)). Adsorption layers can be silicone or active charcoal layers which enrich VOC from gas space. The injection occurs by thermal desorption. Dynamic procedures are also used for enrichment of VOC. In ‘purge and trap’, the volatiles are purged by gas flow and trapped on adsorbent. In ‘spray and trap’, the liquid sample is distributed by spray evaporation into a counter-current gas stream from which compounds are trapped, with the advantage that foaming of the sample is avoided.

Another simple sampling method for on-line monitoring of VOCs from environmental water samples/streams is membrane extraction. When a membrane inlet is used an environmental sample can be pumped directly through a tubular membrane extraction unit, i.e. a separate sampling step is not required. This method has been used successfully for on-line monitoring of VOCs with a transportable mass spectrometer mounted in a boat and for industrial wastewater monitoring.

The enrichment of SVOC can take place on compact filters with an adsorptive surface onto which the sample is directly sucked (solid-phase extraction, SPE) using a plastic syringe or filter disk. The enriched compounds are eluted from the dried collection media by solvents and the extracts are injected. In addition, direct enrichment using an injector liner filled with small amounts of sorbent has been described. Liquid/liquid extraction (LLE) is the most frequently used laboratory procedure applied with accordingly smaller solvent quantities in the form of micro extraction which is also used in the field.

3.3 Soil Samples

Direct thermal desorption with piston-type heaters pressed onto the soil surface has been described as a semiquantitative pre-screening procedure. Thermal desorption of very small subsets (50–100 mg) without previous sample handling (e.g. homogenization) can also be used as a fast screening procedure. However, owing to the small amount of analyzed material both procedures have the disadvantage of being less representative and strongly influenced by matrix effects. It appears to be better to collect discrete samples in the range of 5–50 g and analyze after simple cleanup steps.

Fast, volumetric soil sampling can be performed with disposable plastic syringes (5–10 mL) with the tips cut off. The syringe is filled by penetrating the opened cylinder into the soil. The material is transferred to a glass vial by pushing down the plunger. Sampling in polyethylene bags is a simple procedure suitable when sampling highly contaminated material.

Field-suited procedures have been described in literature for the detection of VOCs and SVOCs. VOCs are detected by means of headspace analysis, ‘purge and trap’ or also by purging without sample treatment. A modified membrane inlet mass spectrometric technique called purge-and-trap mass spectrometry (PAM/MS) has recently been developed for the analysis of VOCs from soil samples. In this method, VOCs are purged from soil samples with an inert gas and the stream is directed via a membrane inlet into a mass spectrometer for analysis.

For SVOCs, extraction is the simplest processing routine. To avoid time-consuming drying of the sample whilst at the same time reaching high yields, polar solvents such as methanol or acetone are used. Polar solvents bind the water content and overcome the binding forces between soil and the pollutant effectively. The sample may be hand shaken, applied to an ultrasonic bath or extracted with a sonicator.

4 MOBILE MASS SPECTROMETRY AND GAS CHROMATOGRAPHY/MASS SPECTROMETRY SYSTEMS

In principle, all routine laboratory mass spectrometers, except for large TOF mass spectrometers, double-focusing magnet mass spectrometers and Fourier transform systems, may be operated on-line or in a mobile laboratory. Systems presented here are mentioned in publications dealing with realistic on-site and field analysis or come from manufacturers whose area of application emphasizes the unique mobile measuring technique by advertisement (e.g. at Pittcon 1997 and 1998).

4.1 On-line Mass Spectrometry

Table 1 lists the on-line mass spectrometers currently available. The simplest mass spectrometers are the leak detectors for gases with capillary vacuum inlet (MS1–4). The main application for these devices is to search for leakages in tanks or other closed systems. This is normally done by detecting a leaking out tracer gas (e.g. a fluorocarbon). Two other mass spectrometers, small, portable prototypes with magnetic and quadrupole array mass separation with valve inlet systems well suited for gas detection have been described (MS5–6) as well as mass spectrometers with differential inlet systems (MS7–9).

An ion trap mass spectrometer (MS7) has been evaluated by the United States Environmental Protection Agency (USEPA). An ion trap mass spectrometer (MS7) has been evaluated by the United States Environmental Protection Agency (USEPA). With this system, mounted in a van, VOCs may be measured on-line in MS/MS mode. In this mode ions of the mother spectrum are further fragmented by collision with a reaction gas. From these fragments the daughter spectrum is recorded, displaying structure details of the target ion from the other spectrum. MS/MS procedures enable compound identification even in complex mixtures without chromatographic separation. Measuring with MS/MS requires a rather complicated measuring strategy and is used when target compounds are known before the measurements start.

Membrane inlet mass spectrometers (MIMS) are listed under MS10–17. Particularly good portability is a feature of the devices dealt with in MS14 and MS15, which can be carried as luggage or as backpack devices problem-free by the analyst during the measurement. Two mobile TOF mass spectrometers have been designed, one with a very compact membrane inlet (MS17) and the other with a rather sophisticated direct inlet system (MS18). The latter operates with laser ionization to analyze aerosols as positive and negative ions simultaneously in two different sections of the mass spectrometers. Systems where special ionization techniques are used (atmospheric pressure ionization (API), atmospheric pressure chemical ionization (APCI) and ion molecule reaction (IMR), see below for details) to enhance the limit of detection limit (DL) are mentioned under MS19, MS21 and MS22.

The DL largely depends on the operation mode of the mass spectrometers. The lowest DLs are achieved in the selected ion monitoring (SIM) operation, since only few signals which are typical for the process are determined. This way substances up to a few ppb in air and 500 ppq in water were detected on-line. The disadvantage of SIM is that only target compounds are recorded and the device is “blind” to components which generate other mass fragments.

Membrane inlets are preferably used to analyze VOCs. If the sample supply as well as the membrane is heated (e.g. 250 °C in the case of MS16), SVOCs such as polycyclic aromatic hydrocarbons (PAHs) are also detectable more or less on-line in short enrichment and desorption cycles.

The DL can be lowered further by longer sample enrichment on a trap and thermal desorption injection. MIMS with pulse-like thermal desorption of the membrane or collecting in a cryo minitrap lead likewise to a higher sensitivity of the devices. This is combined with a high volume direct inlet which requires a high pumping speed which means large pumps and a high power consumption. Therefore these instruments (e.g. MS19) are limited to operation in large containers or mobile laboratories. On the other hand, polar and aggressive substances may be detected which predetermines this device type for on-line measurement for the description of reactive trace compounds in the atmosphere and polar indoor air pollutants.

Other MS devices (MS20–22) are used as automated exhaust analyzing equipment e.g. in engine test stands. MS20 is a very fast TOF mass spectrometer with laser ionization while MS21 and MS22 are supplied with charge transfer or very smooth chemical ionization IMR. The IMR ionization succeeds almost without fragmentation. On the basis of molecular ions a very fast simultaneous on-line detection of several components of the exhaust gas is achieved.

In the fast-growing market of gas sensor arrays (electronic noses) new developments of mobile mass spectrometers (MS10, MS23 and GC/MS6 modified without GC) are used as highly specific on-line array detectors. Mass fragments of the emitted VOC are continuously recorded by scanning 100 to 200 masses and each single mass is considered as a highly specific detector. Using pattern recognition the resulting array is interpreted and compared with the reference pattern for identification of the sample. Examples of applications are the differentiation of beverages and foodstuffs.

On-line mass spectrometers are used for process control in chemical or biological reactors with emission monitoring and control as well as efficient detectors for searching volatile pollutant emissions in the field. Looking for known compounds or mixtures, one or several target ions can be traced next to each other still allowing high time resolution. If unknown materials are affected the identification is often still possible in full-scan mode. If the identification is uncertain, the devices may take over warning functions and prove the absence of toxic materials (e.g. in worker protection).

4.2 Mobile Gas Chromatography/Mass Spectrometry Systems

Table 2 lists GC mass spectrometers currently available. The advantage of on-line MS to measure fast is almost preserved, if separation occurs on very short GC capillaries, in runs from few seconds, duration. The shortening of the chromatographic capillary to ca. 10% of the usual capillary length (of ca. 30 m to a few meters) only leads to a reduction of the separation power to ca. 30%. Thus, despite the reduction of GC run time down to a duration between seconds and few minutes it is still possible to achieve separation powers with $10^3$ to $10^5$ theoretical plates. Most common inner diameters for these short capillaries are below 0.2 mm (microbore capillaries). They are a direct connector between the vacuum part of the mass spectrometer and the injector. It is for this reason that we speak of ‘transfer-line chromatography’. Devices of this type have been constructed from parts of laboratory mass spectrometers (GC/MS1,2) or newly designed as a compact size magnet mass spectrometer (GC/MS3). Fast injection, which is essential for rapid separation, is handled by multiport valves or with a special valveless ambient vapor sampling (AVS) inlet (see Figure 7). The AVS system comprises three concentric tubes whose internal flow controls the vapor sampling process. The innermost tube is the transfer line column to the mass spectrometers. The intermediate tube is cut to extend ca. 2 cm beyond the end of the inner tube. In sampling mode all gas flows are directed towards the transfer line column. Injection is interrupted by switching the flow of the intermediate tube in counter-current direction. Thus, clean gas supplies the transfer line column and the sample gas is prevented from entering the mass spectrometers. Transfer-line mass spectrometers are most commonly used for the detection of VOCs. If the capillary is heated and injection occurs at 275 °C using the AVS it is also possible to analyze SVOCs (e.g. benzopyrene). Transfer-line mass spectrometers are prototypes which are small in size and portable so that they can easily be carried by the analyst.

A truly portable and commercially available GC mass spectrometer is the Hapsite (GC/MS4) with an analyzer weight of 16 kg. It consists of two parts: a pumping station and the analyzer module. For operation the mass spectrometer is evacuated once by an external pump. It is then possible to operate the analyzer module for up to three hours by battery by means of the membrane separator of the MS instrument. The capillaries may be heated isothermally up to 80 °C yielding for a maximum GC run time of about 10 min. The system has recently been evaluated by the USEPA. Transportable GC/MS units with a weight of 60 kg and above (GC/MS5–8) compared with portable ones offer almost the same analytical specifications as laboratory equipment. Such instruments are compact and can be transported in a van. GC/MS methods such as extract injection, thermo-desorption and additional on-line monitoring guided by analytical software are applicable. The inlet systems of transportable MS units are heated. Therefore all substances from VOCs to SVOCs may be analyzed in conventional GC.

The mobile environmental monitor (MEM) (GC/MS5) is a quadrupole mass spectrometer which was modified from military applications during the 1980s. It can handle strong vibrations such as those which occur during transportation in an off-road vehicle and remain fully operable. It is capable of recording spectra of 1–400 m/z/ every 0.5 s. The MS inlet membrane can be heated up to a temperature of 220 °C, the recipient is maintained at 180 °C and pumped solely by an ion getter pump. Three probes are available that can be easily mounted for quick exchange with plug-in connectors. Carrier gas is channelled through the probes by a pump located behind the membrane separator of the MS instrument.

Ambient air enters the injector and passes the GC column serving as the mobile phase for GC. Two of the three probes are provided with 5–15 m GC capillary columns and can be operated in a temperature program mode of up to 240 °C. One of the GC probes contains a thermal desorber for injection of adsorbent-enriched VOC and injection of extracts containing VOCs and SVOCs as well. From the other GC probe evaporable compounds
from untreated samples may be injected using a thermal desorption device which heats the sample between two pneumatically driven heaters.\(^{(12)}\) The third probe is a sniffer sampling device to analyze gaseous compounds in the surroundings of the mass spectrometer. SVOCs are thermally desorbed by pressing the heated head of the probe against the surface of the sample. Separation is performed by means of transfer-line chromatography. The system was evaluated by USEPA in 1988.\(^{(69)}\)

An improvement of the MEM towards higher compactness and a weight minimization to 65 kg is the quadrupole MS EM 640 (S) (GC/MS6). The EM 640 has undergone intensive USEPA testing during their Environmental Technology Verification Program (ETV).\(^{(103)}\) A modification of this instrument, called the EM 640S, has a direct inlet together with a turbo-molecular pump and a roughing pump integrated in the system. Both versions are capable of recording spectra of 1–640 \(m/z\) every 0.5 s. SIM operation is also possible. A carrier gas control unit enables operation of the GC capillaries with externally attached gases with split/splitless injection or with a thermal desorber for adsorbents. The maximum temperature of the GC temperature program is 270 °C. The updated software permits multitasking. The probes consist of two compact GC modules with GC separation capillaries of different separation phase and lengths of up to 15 m. The GC probes can be easily mounted for quick exchange with plug-in connectors. The system was evaluated by USEPA in 1997.\(^{(103,171)}\)

The GC/MS systems (GC/MS7) designed by the company Viking are accommodated in a suitcase or a sturdy housing. They are extremely compact units with a weight of ca. 60 kg. The device designed from a Hewlett Packard MSD is evacuated with an internal turbo-molecular pump and an additional mechanical pump attached externally over a vacuum tubing. Spectra within the mass range of 10–650 \(m/z\) can be recorded every 0.3 s. The different software-controlled inlet systems offer a high standard of convenient operation. In addition to a membrane inlet for gases the system has a direct inlet GC equipped with one split/splitless extract injector, an integrated enrichment unit for gaseous samples and a thermal desorber for adsorbent traps. GC capillaries up to 25 m and oven temperature up to 280 °C are used. The Spectra Trak 672 model was tested thoroughly in the context of the USEPA ETV Program.\(^{(103,176)}\)

Within the EUREKA Project EU 674 new technologies for the application of mobile analytical laboratories are being developed. The VG/Fisons MD 800 (GC/MS8) is part of the device’s equipment which is a commercial laboratory GC mass spectrometer being modified for mobile application by mounting it into a feed framework. Tests have been performed, but a report has not yet been presented.

Mobile GC/MS systems allow analyses to be carried out in the field with a quality which is hardly inferior to that of laboratory instruments. Because of the various analysis possibilities in on-line screening of VOC to SVOC GC/MS runs, these devices are designed for applications with highly toxic materials (e.g. chemical warfare agents) or scenarios which have a broad range of materials (e.g. in fire plumes, chemical emergencies or on unexplored chemical waste dumps).

5 QUALITY ASSURANCE/QUALITY CONTROL PROCEDURES AND COMPARISON OF ON-SITE/IN SITU MEASUREMENTS WITH OTHER METHODS/FIXED LABORATORY METHODS

The use of proper quality assurance/quality control (QA/QC) procedures together with analysis performed in a mobile laboratory and/or with mobile instruments is as important as when the analysis is performed in a stationary laboratory.\(^{(12)}\) One could also easily argue that the QA/QC protocols are even more important in a mobile laboratory. This is partly due to the fact that the field conditions are assumed to be not as well controlled as the conditions in a stationary laboratory; for example the possible risk of contamination of instruments, blanks and samples may be higher in a mobile laboratory.\(^{(12)}\) In addition, the users and developers of mobile instruments are responsible for using proper QA/QC methods in order to produce high quality data at all times which will accelerate the acceptance of the use of mobile instruments in environmental monitoring. This is very important since governmental offices and research institutes which stipulate environmental regulations are often reluctant to accept innovative techniques in place of the traditional well-known and thoroughly tested stationary laboratory instruments and methods.

The current literature on mobile mass spectrometers shows that in most cases the same customary QA/QC methods, such as initial and continuing calibrations, laboratory duplicates, labeled internal standards, matrix spikes and various types of blanks, as those used in stationary laboratories are also used with mobile mass spectrometers.\(^{(12,35,170,184–187)}\) Some research groups are also using a few added QA/QC methods such as:

1. automatic daily tuning of the mass spectrometer;
2. using only disposable equipment for sampling and sample handling;
3. developing analytical methods adapted to the needs of on-site conditions;
4. analyzing a reference sample twice a day;
5. keeping a control chart of these measurements in order to assist identification of possible instrumental problems or other errors.\textsuperscript{11}

A continuous method for the mass spectrometer function check has also been introduced. In this method the signal of argon (m/z 40) being one component of the carrier gas is continuously followed in order to control the mass scale tuning and the sensitivity of the mass spectrometer.\textsuperscript{15,185 – 186} An important aspect of the QA/QC protocols is their proper use and this will happen only if the personnel using mobile instruments have adequate knowledge and experience in using the instruments. This can only be achieved through proper training of the personnel as is currently the case, for example, with firefighters in Hamburg, Germany.\textsuperscript{11}

Comparison of the quality of the data obtained using mobile mass spectrometers with the data obtained using stationary laboratory mass spectrometers or with the data obtainable using other mobile instruments is a very important part of the validation of the performance of mobile mass spectrometers.\textsuperscript{35,67,68,76,104,108,171,172,174,184,186,188,189} These comparisons include determination of VOCs from air, soil gas, soil and water; measurement of PAHs from soil;\textsuperscript{68} measurement of phenols from soil;\textsuperscript{35,67,184,186} measurement of pesticides from soil and sediment;\textsuperscript{190} In addition, the USEPA has performed a thorough validation of two different commercial mobile GC mass spectrometers in the analysis of VOCs from water, soil and soil gas.\textsuperscript{171,176} In most of these studies the data obtained using mobile mass spectrometers have been compared with the data obtained using stationary laboratory benchtop GC/MS instruments; however, comparisons with various GC methods and with a high-performance liquid chromatography (HPLC) method has also been made. Normally the agreement between the various methods has been very good; only in the case of analysis of VOCs has any significant discrepancy been observed. A simple explanation for the discrepancy is that owing to the large volatility of VOCs they are easily lost from the samples unless very careful sample storage, transportation and preparation methods are used. However, the USEPA instrument validation studies have shown that in the analysis of VOCs from various matrices, mean accuracy is better than 40% and precision values better than 50% can be easily obtained.\textsuperscript{171,176} In the following a few examples of these comparison studies are discussed in more detail.

In Tables 3 and 4 the results obtained in the analysis of VOCs from air and soil are presented, respectively. The on-site results presented in Table 3 were obtained by collecting the samples to charcoal sorbent tubes, thermally desorbing the analytes into a mobile GC/MS instrument and utilizing modified USEPA TO1 and TO2 methods.\textsuperscript{174} The off-site results in Table 3 were obtained by collecting the samples to charcoal sorbent tubes, extracting the analytes by CS₂, injecting the liquid into a benchtop GC/MS instrument and using modified National Institute for Occupational Safety and Health (NIOSH) 1500, 1501 and 1003 methods. From the results presented it is easy to notice that the agreement between the data is good even though slightly different analytical methods were used. For some analytes the off-site results show slightly lower quantitative values, probably due to the evaporation of the analytes during the sample handling. The loss of VOCs due to sample preparation, for example, with firefighters in Hamburg, Germany.\textsuperscript{11}

Figure 8 Summary of an interlaboratory comparison of 44 laboratories in analysis of PAHs from soil utilizing the mobile GC/MS method (sample i.d.1) and the stationary laboratory GC/MS: GC flame ionization detection: HPLC: 0 methods. Mean concentration: all laboratories; each laboratory. A sum of 16 PAH compounds as defined in the USEPA method 610(1984) is presented. (Reproduced from 'Fast GC/MS Field Screening for Excavation and Bioremediation of Contaminated Soil', G. Matz, W. Schröder, Field Analyt. Chem. Technol., Copyright © (1996 John Wiley & Sons Inc.).)

storage and transportation is very clearly seen in the results presented in Table 4. In the table quantitative results for trichloroethene measured from soil samples by on-site headspace gas chromatography (HS/GC) and on-site and off-site purge-and-trap gas chromatography/mass spectrometry (PT/GC/MS) are presented. Note that the agreement between the analytical results obtained on-site by HS/GC and PT/GC/MS is very good but the off-site PT/GC/MS results differ considerably from the on-site results. The only reasonable explanation for the difference was the loss of VOCs during the sample handling steps, which is a phenomenon observed quite frequently. This fact is very clear proof that in some cases on-site measurements can provide higher quality data than the off-site stationary laboratories.

In the analysis of SVOCs the agreement between the results obtained using mobile mass spectrometers and the results obtained by various analytical methods in stationary laboratories are very good. As a representative example of the very good agreement, the results of an interlaboratory comparison study in the analysis of PAHs from soil samples are presented in Figure 8. There were 44 different laboratories participating in this study. The results obtained by the mobile GC/MS instrument agreed well with the results obtained by the other laboratories. Data obtained in the field are very close to the mean concentration of all the laboratories, i.e. the value which is most probably the correct concentration.

6 EXPERIENCE GAINED FROM ANALYTICAL CAMPAIGNS WITH MOBILE SYSTEMS

The actual efficiency of on-site analysis largely depends on the qualifications of the users or on their practice in the particular application. Complex sample preparation steps from the laboratory must be simplified and shortened. The sequence of QA/QC analyses must be a fixed constituent of the analytical process. Standardized analytical methods and software-guided methodologies from the sampling to the result of analysis may offer assistance. The diverse information supplied, particularly by mobile GC/MS systems, in the rapid sequential determination from different matrixes and types of analyte requires very good organization of the resulting data. Presentation of the results must be documented in such a way as to allows immediate access, including current status of the QA/QC analyses and all device parameters. Great effort towards developing non-standard software is necessary here.

The mobile GC mass spectrometer supplies important information to the sampling point at a high repetition rate, and this must be used immediately for good reason. So the analytical team easily becomes a decision-maker. Since the sampling, the work in excavation or handling of chemical emergencies is directly controlled by the result of the analysis, cooperation with the drilling team, geologist, environmental protecting agency or head of the fire fighting team must be clearly determined before the first analysis.

Analysis campaigns with mobile GC/MS have already demonstrated the advantages of analytical investigations in the field. Excavation following the borders of contamination results in a drastic reduction in toxic material...
which has to be disposed of, inhomogeneity of the investigated site can be described as deciding between sampling strategies and the success of bioremediation can be better proved by statistically based evaluation from multisampling and many analyses. With round robin tests and measurement campaigns parallel to laboratory investigations it has turned out that with VOCs more accurate results were obtained by local analysis owing to problematic sample storage. Although, generally, mobile mass spectrometers are more expensive than appropriate laboratory instruments, savings of up to 70% can be made in relation to laboratory analysis by careful cost balancing over the whole analysis campaign. Taking into account that 80% of the analysis error is derived from taking, transporting or storing the sample, the application of mobile systems appears as the best means of more reliable environmental analyses.

7 CONCLUSION

In this article various aspects including sampling, analytical methods, quality assurance/control and instrumenta
tion, of on-site/in situ environmental measurements using mobile mass spectrometers have been presented. It has also been shown that mobile mass spectrometers have produced valuable data in many different kinds of applications, e.g. monitoring of environmentally significant compounds from water, air and soil, and identification and quantification of possible toxic compounds produced in fires or released during chemical spills. The quality of the data obtainable using mobile mass spectrometers has also proved to be as good as obtainable with the traditionally used stationary laboratory GC/MS methods or with other chromatographic methods. In addition, mobile mass spectrometers currently commercially available are briefly presented.

The future will no doubt bring advances to all the sectors mentioned above but from the point of view of a research scientist the most interesting advances will surely take place in the instrumentation sector. There are at least three different very important mass spectrometer development areas, which are also heavily dependent on the development of interrelating scientific work such as the development of electronics, computer hardware and software, vacuum technology and battery technology.

One is the improvement of the sensitivity of the mass spectrometers. Looking back on the history of the development of mass spectrometers, we perceive that typically one order of magnitude better sensitivity has been obtained per decade of development of new instruments. This same trend is also likely to continue in the future.

Another trend is that more and more versatile instruments have been produced. This is especially true when considering the development of quadrupole ion traps. This advance will also continue in respect to types of mass spectrometers other than the ion traps. One of the latest trends in the development of all types of instruments, including mass spectrometers, is miniaturization of them and building them on a silicon chip. For example, at the 46th ASMS Conference on MS and Allied Topics there was a special session about miniaturizing mass spectrometers [Session “Miniaturizing Mass Spectrometers”, 46th ASMS Conference, Orlando, Florida, May 31–June 4, 1998]. In the session, designs of miniature magnetic sector, quadrupole and time-of-flight instruments were presented. On the other hand, mass spectrometer developers know that there are physical limitations which accompany miniaturization such as coulomb interactions limiting the ions’ focusing, mass resolution and sensitivity, limits of the lowest detectable current, range of analytes dependent on heating and the power consumption. This development is moving quickly forward since already in this session data obtained with a quadrupole mass spectrometer made on a silicon chip has been presented.

The mass spectrometric development will produce mobile mass spectrometers that are capable of continuous long-term monitoring of environment, and truly miniaturized, i.e. hand-portable, and easy to use mobile mass spectrometers, which can be used for identification and quantification of unknown compounds in environmental accidents, fires, chemical spills and other situations where rapid reliable analytical results are required.

Improvement of the current, and development of new, sampling methods is another important research area in future. It is believed that especially sampling methods such as membrane inlets and other direct introduction methods will become more popular owing to their ease of use and the fact that with direct methods all the possible changes of the samples caused by the sample handling steps are minimized.

When all the foreseen development steps have been taken into consideration we can conclude that the use of mobile mass spectrometers will certainly increase considerably in the future in universities, research institutes and industrial laboratories. All the comparisons between mobile and laboratory GC/MS point out the advantages of field analysis with respect to quality, reliability, speed of analysis and costs. A definite milestone for the rapid increase in use of mobile mass spectrometers for environmental analysis will be the time when governmental or intergovernmental (e.g. European Union) agencies accept, introduce and demand standard methods for environmental analysis which are based on mobile mass spectrometers. In addition, the range of application areas of mobile mass spectrometers will...
increase, for example one certain new application area will be direct measurement of biological warfare agents from various matrices. In conclusion, developers, users and manufacturers of mobile mass spectrometers can look forward to a bright future.

The existing radon and radon progeny measurement instruments are described in this article. The various methods and instruments used depend on whether radon or radon/thoron progeny or daughter products are being measured, the duration of the measurement, whether short-term or long-term and the type of radiation being detected (alpha, beta, or gamma). The modes of detection used include the following: activated charcoal radon monitors, electret ion chamber, registration of nuclear tracks in solid-state materials, liquid scintillation, ionization chambers, scintillation detectors with zinc sulfide, ZnS(Ag), alpha particle spectrometers with silicon diodes, surface barrier or diffused junction detectors, and gamma-ray spectrometry with NaI(Tl) scintillation crystals or germanium lithium (GeLi) semiconductor detectors, fiber optics sensors and glass. The advantages and disadvantages will be described for various portable instruments used for measuring radon, thoron, and their daughter products. Comparison studies among the radon monitors will be included.

The reader is referred in particular to George(1) and National Council on Radiation Protection (NCRP) Report 97(2) for additional information.

1 INTRODUCTION

Radon, the inert gaseous element created from the radioactive decay of $^{226}$Ra and $^{232}$Th, itself decays with a short half-life (3.8 days for $^{222}$Rn and 55.6 s for $^{220}$Rn) to produce a series of short-lived daughter products. Measurement techniques generally determine the radon concentration (Bq m$^{-3}$ or pCi L$^{-1}$) in air or water or the total energy of the alphas released by the complete decay of the radon daughter products (RDPs); the quantity is usually expressed in terms of the working level (WL).

Table 1(3,4) shows the radiometric properties of $^{222}$Rn, $^{220}$Rn, and their short-lived daughter products. Details can be found in NCRP Report 58(3) and Shleien.(4) Radon and its daughter products, when inhaled, deliver a significant alpha radiation dose to bronchial tissue that has been implicated in radiogenic lung cancer. Radon also has an affinity for bone tissues.

Several quantities are almost uniquely used in the measurement of radon and the daughter products:

1. The WL is the total amount of energy which would be eventually released by the alpha particles emitted by short-lived RDPs. It is defined as the combination of radon daughters in one liter of air that will result in the emission of $1.3 \times 10^5$ MeV of potential alpha energy (2.08 $\times 10^{-5}$ J m$^{-3}$). The WL is the common unit for expressing radon daughter dose rate, originally in uranium mines, but now in environmental exposures as well. Under equilibrium conditions, 3700 Bq m$^{-3}$ (100 pCi L$^{-1}$) of radon will produce 1.0 WL in approximately four hours. The quantity is historically related to its use with measurements made of the air in uranium mines.

2. The equilibrium equivalent concentration (EEC) is the radon concentration, in equilibrium with the short-lived daughters, that would have the same potential alpha energy concentration (PAEC) per unit volume as the existing mixture. Numerically, it is calculated from measured concentrations of the daughters (Equation 1):

$$\text{EEC} = 0.105[A] + 0.516[B] + 0.379[C]$$

where EEC is expressed in Bq m$^{-3}$ or pCi L$^{-1}$ and [A], [B], and [C] are the respective concentrations of the $^{218}$Po, $^{214}$Pb, and $^{214}$Bi daughters in the same units. Equations (2–4) may be used to calculate the PAEC in WLs from a particular $^{222}$Rn concentration in EEC.

$$\text{WL} = \frac{\text{EEC (in Bq m}^{-3}\text{)}}{3700}$$

$$\text{WL} = \frac{\text{EEC (in pCi L}^{-1}\text{)}}{100}$$

$$\text{Jm}^{-3} = \frac{\text{EEC (in Bq m}^{-3}\text{)}}{1.8 \times 10^8}$$
The cumulative exposure is expressed in terms of measure this activity and relate the results to the total may, however, be ingested. Also, several techniques to
are to be estimated unless it is resuspended. Some of it
eration when radiation doses from inhaled radioactivity

aerosol particles in the air. They may also be deposited
products is that the high electrical charges of the newly
Tl-208 3.1 min 0.7–1.8 (beta) 0.01–2.6
Note: The betas are maximum energies. (Please see Shleien et al.,(4) for electrons and individual betas.)
See the Figure 10.1 in NCRP 97(2) for the contributions of RaA(218Po), RaB(214Pb) and RaC(214Bi) to the PAEC as a function of time from initially pure 222Rn. The primary reference is Evans(18) and the secondary reference is NCRP 97.(2) Also, see Figure 10.2 in NCRP 97(2) for the build-up and decay of alpha activity of RaA(218Po) and RaC(214Po) from individual isolated RaA, RaB(214Pb) and RaC(214Bi), each having an initial decay rate of 0.17 Bq (10 disintegrations per minute). The primary reference is Holaday et al.,(19) and the secondary reference is NCRP 97.(2) The author recommends NCRP 97(2) for a very good background on measurement of radon and radon daughters in air.
3. The cumulative exposure is expressed in terms of the working level month (WLM), where WLM = WL × (hours exposed/170), since uranium miners were considered to have worked 170 hours in a month. 1 WLM = exposure to 1 WL for 170 h. A more detailed discussion of these quantities and units appears in NCRP Report 97.(2)

Another concern about airborne radon and its daughter products is that the high electrical charges of the newly created daughters, especially 210Po, cause a significant fraction to become attached to dust, water and other aerosol particles in the air. They may also be deposited on the surfaces of walls, ceilings and objects in the vicinity (“plateout”).

The plateau radioactivity is thus removed from consideration when radiation doses from inhaled radioactivity are to be estimated unless it is resuspended. Some of it may, however, be ingested. Also, several techniques to measure this activity and relate the results to the total exposure from radon over an extended period have been developed.

A measure of the fraction of radon daughters attached to aerosol particles is the “equilibrium factor”, F, the ratio of the PAEC in the existing mixture to that which would exist if all short-lived daughters were in equilibrium with the radon present (=EEC/[222Ra]). The value of F depends on the ambient environmental conditions such as humidity, temperature, the amount of turbulence, infiltration and exfiltration. It also changes with time as the relative abundance of the various radon daughters changes due to radioactive decay. The NCRP has recommended values of 0.4 for indoor environments, and 0.7 for outdoor environments when actual measured values are not available. The United States Environmental Protection Agency (USEPA) uses a range of 0.3–0.7 for their equilibrium ratio (ER) and assumes the midrange value of 0.5 for indoor environments.

### 2 SAMPLING STRATEGIES

#### 2.1 Radon Compared with Radon Progeny

Air concentration measurements are made much more frequently of radon than of the radon progeny. Although sampling and analysis for radon progeny are more difficult and more costly than that of the parent radon gas, they are required for certain situations where a more precise assessment of the radiation exposure is needed. Measurement of radon air concentrations must consider that three isotopes, 219Ra(220Ra), 220Ra(222Ra) and 222Rn from thorium, half-life of 55 s, are usually not present.

In some cases, both the radon and the daughter concentrations are measured. One method is the two-filter method.(14) Ambient air, containing a mixture of radon and daughters, is drawn through the first filter to remove the radon progeny. The radon containing air passes into a decay chamber, where the daughters produced are collected on a second filter. The concentration of radon (on the first filter) and that of the radon progeny (on the second filter) can be counted separately by alpha spectroscopy, scintillation counting, or a passive detector.(5)

#### 2.2 Sampling Time

There are three time regimes for sampling. It should be noted that in all three cases, the results are averaged over the sampling time. The sampling time can vary from seconds in the case of sniffing to seconds to minutes for grab sampling to days, months or longer for integrated time measurements.
2.2.1 Grab Sampling

The advantages of grab sampling for radon gas are the quick delivery of results and that the sampling equipment is usually very portable. The disadvantages are that the sample period is too short to use as a short-term measurement (i.e. less than 48 h). The lower limit of detection (LLD) for most grab sampling methods is a few tenths of a pCi L⁻¹, the expected precision is quite low (about 25%) unless counting times on the order of several hours are used (about 10% at or above 4.0 pCi L⁻¹). The individual sample cells may need calibration as well as the analysis systems. Individual background levels for each cell may need to be established. In addition, spiked samples and duplicate samples may be necessary to ensure acceptable quality control on the results.

Grab sampling is typically conducted by collecting the air to be studied in a 5–15-liter container that is sent to a laboratory for analysis. The radon can be concentrated for easier or more accurate analysis by passing the air sample through an activated charcoal trap submerged in liquid nitrogen. At this low temperature, radon is retained on the charcoal while the air passes through. The trap is then warmed in the presence of helium and the radon transferred to a counting cell or ionization chamber for analysis. There is usually a wait of four hours or more to allow the collected radon to come to equilibrium with its short-lived daughters although recent advances in the development of computer-based analysis systems have somewhat reduced the waiting time. Instruments used to measure WLs usually draw air through a filter to collect the daughter products, which are then analyzed.

Grab sampling can be used in a “sniffing” mode, say as a diagnostic tool for finding entry routes of radon gas, by measuring the sample almost immediately after it is taken. The technique provides a quick, but imprecise, measurement to identify relative differences between multiple measurements.

Practical concerns about grab WL devices include the following: the air pump must be well regulated, requiring routine calibration of the pumps and flowrates with a complete calibration annually. Typical airflow rates range from 2 lpm to 25 lpm, but they can be lower or higher. The sampling period must be precisely controlled and the delay time between the end of sampling and start of analysis (counting) accurately recorded. Care must be taken so that the exposed face of the filter faces the detector. The complex operating procedure requires a trained operator. The technique generally cannot be used for short-term or long-term measurements that are required by agencies such as the USEPA.

Examples of two of the more common protocols for grab sample WL analysis are the following:

2.2.1.1 Kusnetz Count for 10 min, 40–90 min after the end of sampling; the WL averaged over the sampling time is calculated from an empirical algorithm usually by a computer.

Both filters are actually measuring progeny concentrations—the first filter measures the actual progeny concentration, and the second uses the build-in of the progeny from pure radon to measure the radon concentration.

The Kusnetz method and modifications are very well explained in NCRP report 97.

2.2.1.2 Tsivoglou Count from 2–5 min, 6–20 min, and 21–30 min; the WL averaged over the sampling time is calculated along with individual activities of the daughter products ²¹⁴Pb, ²¹⁴Po, and ²¹⁸Po.

2.2.2 Continuous Sampling

In continuous sampling, the air is drawn or allowed to diffuse first through a filter to remove the radon daughters then through a sensitive volume where the analysis is performed. There is relatively good precision with most devices. Continuous sampling devices can track hourly variations (or more often depending upon the device) and are frequently controlled by computers that record the results and parameters for downloading or analysis at a later time. The results can reveal evidence of tampering or improper ventilation. Typical sampling periods range from 48 h to months if the filter is maintained or replaced periodically. The continuous sampling techniques can be used to measure and record variations in the WLs with
time as well as the individual radon and thoron decay products.

In active systems, the air is drawn through the sensitive volume by a pump; in passive systems, the air is allowed to diffuse into the volume, a process that requires about 4 h to come to equilibrium. The typical sampling period is 48 h, of which the data from the last 44 contiguous hours are used.

Continuous radon monitors are relatively costly and require a trained operator. Some units do not have good precision around the 4.0 pCi L\(^{-1}\) concentration used as an action level by the USEPA. Also, since the air is in the chamber for a short period, the short-lived thoron is counted along with radon. Consequently, the readings must be used qualitatively only unless one compensates for the presence of the thoron. The four-hour ramp-up time for passive systems may be a significant drawback. Continuous monitoring in dusty, smoky, and high-humidity environments should be avoided or carefully maintained. If the results from WL monitors are converted to pCi L\(^{-1}\), the ER or equilibrium factor, \(F\), must be measured or assumed.

The LLD of the typical continuous sampling device is 1.0 pCi L\(^{-1}\) or less, with a precision of \pm 10\% at concentrations of 4.0 pCi L\(^{-1}\) or greater. The devices are usually calibrated annually, with semi-annual crosschecks. If scintillation cells are used as detectors, the background counting rates must be monitored. The devices that measure WL have sensitivities of 0.01 WL or less with a precision of \pm 10\% at 4.0 pCi L\(^{-1}\) or higher concentrations. The background level of the WL instruments should be determined at least after every 168 h of use, taking care to draw clean or aged air or nitrogen through the filter.

2.2.3 Integrating Sampling

Integrating samples provide a single value of either radon concentration or WL averaged over the exposure period. They can also provide a measurement of total exposure (usually in WLM) for the period of that exposure. The length of the period can be as short as a few days or can be of the order of many years. Although there are active devices, the most commonly used monitors are of the passive type. Such devices include canisters or other vessels containing activated charcoal, alpha track detectors, and charcoal liquid scintillation detectors, and charcoal canisters. Because radon levels vary from day to day and season to season, due to such things as weather changes, opening and closing of doors, the type of air conditioning/heating systems and the lifestyle of the family, a short-term test is less likely than a long-term test to provide an adequate measure of the annually averaged radon level used by most public health agencies for decision making purposes. A short-term monitoring period is more likely to detect an unrepresentative peak or valley in the radon concentration than the long-term test. However, the quick results provided by the short-term tests make them very popular for use in real estate transactions and initial sampling.

2.2.3.1 Short-Term Testing

Short-term tests remain in place from 2 to 90 days, depending on the device. Common passive devices for short-term testing include alpha track detectors, charcoal canisters, charcoal liquid scintillation detectors, and electret ion chambers. Because radon testers may use any of these devices to measure the home’s radon level.\(^{(6)}\)

2.2.3.2 Long-Term Testing

Long-term tests remain in place for more than 90 days. Alpha track and electret ion chamber detectors are commonly used for this type of testing. A long-term test provides results that are more representative of an annual mean value for radon concentrations or WL. In the USA, long-term tests are frequently used to confirm initial short-term results between 4 pCi L\(^{-1}\) and 10 pCi L\(^{-1}\), because the USEPA recommends remedial action if the average annual radon concentration in occupied areas is greater than 4 pCi L\(^{-1}\).

2.2.4 Measurement Location and Conditions

Short-term measurements in buildings are generally made under closed building conditions, i.e., windows, outside vents, and external doors closed, and internal–external air exchange systems off. These conditions should be present at least 12 h before the beginning of the tests. The measurements should be made in areas away from drafts and extreme temperature conditions. The measurement location should be at least 90 cm from windows and other openings, 30 cm from external walls, 50 cm from the floor, and 10 cm from other objects. If possible, it should be made in the general breathing zone area (2–2.5 m from the floor).
3 THEORY AND OPERATING PRINCIPLES OF THE DETECTORS

3.1 Passive Detectors

3.1.1 Activated Charcoal Detectors

This detector typically consists of a cylindrical “salve” canister, containing 25–200 g of activated charcoal although there are several different configurations. The charcoal has a high affinity for radon that adsorbs on its active sites. The canister is prepared and sealed until the exposure period begins. It is placed in the test area with the top removed for a period of three to four days. During this time, the radon diffuses into the charcoal and is adsorbed. At the end of the exposure period, the canister top is replaced, sealing the canister again. A period of at least three hours but not exceeding seven days is allowed before the canister is analyzed. Analysis is done by placing the canister before a gamma analysis detection system, usually consisting of a NaI(Tl) scintillation crystal and a multichannel analyzer calibrated to measure the intensity of the gammas from one or more of the daughter products, usually $^{214}\text{Pb}$ and $^{214}\text{Bi}$. The LLD for these systems ranges from 3.7 to 7.5 Bq m$^{-3}$ (0.1 to 0.2 pCi L$^{-1}$) for an exposure period of four days. Occasionally, other detectors, such as high purity intrinsic germanium (HPGe) semiconductor detectors are used instead of NaI(Tl).

Some charcoal detectors have a diffusion barrier that slows the diffusion of the radon and filters out the daughter products. The barrier also slows the diffusion of atmospheric water vapor that competes with radon for the charcoal sites and extends the period of integration to about seven days. According to Cohen,$^6$ a typical collector with 25 g of charcoal, at intermediate humidity and temperature, collects 0.068 Bq per Bq m$^{-3}$ of radon in the air (68 pCi per pCi L$^{-1}$) after one week’s exposure.

A second activated charcoal detection method uses collectors containing 1–2 g of charcoal that is analyzed by liquid scintillation counting (alpha/beta analysis). The radon is eluted from the charcoal into an organic solvent by liquid scintillation counting (alpha/beta analysis). The $^{222}\text{Rn}$ decay results in the release of two alpha particles and two beta particles each of which may be detected by the analyzer. The LLD is about 5 Bq m$^{-3}$ (0.14 pCi L$^{-1}$).

The activated charcoal detector is one of the least expensive devices for radon measurement. Each canister costs about $1 (US) and the charcoal can be regenerated to drive off the radon and organic gases and recycled. A gamma analysis system generally costs ~$20,000 (US). Since the deployment and retrieval of the detectors requires only brief instructions and no training, the detectors are very popular for screening of private houses and buildings. The USEPA estimates that over 50% of screening measurements in the USA use the charcoal detector. The detectors are placed by homeowners, house inspectors, or real estate agents, then recovered and mailed to a processor for analysis.

Since the radon adsorption processes are temperature-dependent and compete with water vapor and other molecules, these detectors are used only in indoor environments that experience moderate environmental fluctuations. The correction for humidity is determined by obtaining the weight gain of the charcoal during the exposure period. It is rarely larger than ±6%. Since the average correction is only about 3%, the step is usually omitted. The correction for temperature is 1.5% per degree Fahrenheit, with an uncertainty of 5%.

Because the response of the detectors is controlled by the diffusion of the radon, they are not true integrating devices if radon concentration peaks and valleys are dramatic. Their use is limited to short-term integrated time sampling, so they may miss changes in radon concentration due to rainfall or long-term barometric pressure variations. They must also be analyzed within a very short time after exposure.

Another potential problem is that of deliberate tampering with the sampling process, by such actions as increasing the area ventilation rate by opening windows or doors or activating an exhaust fan when the canister is exposed, locating the detector in a nonrepresentative area or covering the detector for part of the exposure period. None of these deceptive practices will be detected by the results of the analysis.

3.1.2 Electret Ionization Chambers$^8$

These detectors are variations on the common ionization type detector (see below) in which the radon decay radiation particles create charged pairs in the air of the active volume of the detector. The charges collected by one electrode are measured to determine the total activity averaged over the exposure time. In these passive devices, the electrical potential is supplied by a Teflon$^6$-based electret rather than an active electrical power supply.

The electret ionization chamber consists of a conducting plastic chamber that contains the electret. When the detector is positioned and the chamber opened to the ambient air, radon diffuses through a filter into the chamber. There it decays, with the radiation produced by it and its daughter products generating ion pairs in the air. The electrons produced in the ionization events are drawn to the electret and consequently reduce the potential difference (voltage) on the surface of the electret. This change in the electret surface voltage is measured by a separate calibrated voltmeter and corresponds to an activity integrated over the period of exposure. The device is
used until the electret surface potential is depleted. The electret is then replaced.

The electret ion chambers may be used in either indoor or outdoor environments since they are less sensitive to environmental fluctuations such as temperature and humidity. They can be configured for short-term measurements of two to seven days as well as for long-term measurements of three to six months by using electrets of varying thickness. If the electret voltage is not depleted, the same unit can be used to make sequential measurements by measuring sequential drops. The devices do not need to be analyzed immediately after exposure.

One disadvantage is that because the detectors are sensitive to all types of natural background radiation, a correction must be made. Another is that the electret of the device can be damaged by touching the surface by contamination or by physical impact.

There are two manufactured electret-based ion chambers, Rad Elec’s E-PERM and the Ra Dome™ chamber. The short-term E-PERM devices have sensitivities of 7 Bq m⁻³ (0.2 pCi L⁻¹) for a three-day exposure. The Ra Dome™ is a long-term device that measures 150 Bq m⁻³ in 90 days.

### 3.1.3 Alpha Track Etch Detectors

This group of passive detectors is based on the phenomena that charged particles, especially alpha particles such as those emitted during the decay of radon and its daughters, leave a track of disrupted chemical bonds as they penetrate into solid materials and give up their energy. In certain materials, these tracks can be made visible by chemical etching because they etch at a significantly faster rate than the unaffected material. The areal density of the tracks can be correlated to the total exposure of the material to radon and its daughters (tracks cm⁻² per Bq d⁻¹ m⁻³).

Cellulose nitrate (LR-115) and allyl diglycol carbonate (CR-39) films are two of the most commonly used materials. The chemistry of the etching process, usually in an NaOH solution, and the calibration for radon exposure for these materials is probably most established for these two materials. The track density is determined by manual scanning under a microscope or with the use of a computer-based optical scanning program.

The permanence of the track density image and the capability of the detectors for integrating measurements over extremely long times are the method’s chief advantages. The tracks left by beta and gamma radiation are not imaged by the etch process because they are not large enough to exceed the threshold for imaging in the etch process. Therefore, ambient background corrections are not required. The cost per detector is relatively low and the simplicity and robustness of the detector have resulted in its widespread use for long-term integrating measurements of radon concentrations. They are easily distributed and, in the USA, they can be returned for processing by the postal mail system.

The drawbacks include the need for labor-intensive chemical or electrochemical processing and the variations in the material response due to thickness, acquired background and temperature variations. The detector calibration is also sensitive to the altitude of the measurement because the alpha particle range increases as the ambient air density decreases. At higher altitudes, the average energy the alphas deposit in the detector thus increases.

The track etch material, which varies in surface area, is usually mounted in the bottom of a chamber with one end open to the ambient air. The tracks are created by that fraction of the alphas emitted during the decay of the radon in the chamber and the daughter products (¹²⁶⁰Po and ²¹⁴Po) produced that impinge on the detector with enough kinetic energy to create a track large enough to be imaged after etching. The chamber must be configured so that areas of persistent electrical static charge are eliminated as a source of interference with the accumulation of the tracks. Cohen has found that the calibration factor for nuclear track detectors has been found to vary unpredictably with a standard deviation of 16%, presumably due to electric charge effects associated with use of plastic cups. For radon concentration measurements, a filter may remove the ambient daughter products so that only radon diffuses into the chamber. For WL measurements the opening is unfiltered and the ER is either determined or assumed (usually to be 0.5).

Track etch is not as sensitive as other techniques. For example, reasonably accurate environmental measurements require exposure periods of three months to one year. The range of detection is 0.2–20 000 pCi L⁻¹ months (0.004 to 400 WLM at an ER of 0.5) for a coffee-cup-sized detector or 0.4 to 600 000 pCi L⁻¹ months (0.008 to 1200 WLM) for a pill-box-size detector. Typical calibration factors are 0.001 tracks per Bq m⁻³ day (0.0372 per pCi L⁻¹ day). A 90-day exposure at 37 Bq m⁻³ (1 pCi L⁻¹) gives an average of 3.3 tracks in addition to 0.4 tracks from background, a total of 3.7, with a standard deviation of 1.9, and a percentage uncertainty of 58%.

The precision, especially at low concentrations, can be improved by increasing the number of microscopic fields counted. For example, if the background is 4 tracks per field where the total counted tracks is 8 per field then counting 1 field gives a precision error of ±75%, counting 3 fields, ±50%, and 10 fields, ±25%.

The track etch technique is not confined to plastic detectors. Recent advances have been made, primarily in Europe, in applying the procedure to glass such as...
that in aged mirrors and picture frames, and with less success, windows. If the glass has been exposed over a period of years, then the track density can be correlated to the integrated exposure for the individuals occupying the same rooms. Although there are many influences on the accuracy of this technique, the promise of obtaining at least a first approximation of the long-term exposure of individuals has captivated several researchers.

Another technique involving aged glass involves the measurement of the $^{210}\text{Po}$ activity imbedded in the surface of the glass by the recoil energy of the parent. The glass surface is etched with hydrofluoric acid to remove the $^{210}\text{Po}$ which is then measured directly by mass spectrometry or by alpha liquid scintillation analysis. Jones found the technique useful for exposures greater than 259 pCi L$^{-1}$-years with a correlation of 0.97 in a controlled laboratory experiment.

### 3.1.4 Thermoluminescent Dosimeters

Thermoluminescent (TL) materials are commonly used to measure integrated radiation dose in a wide variety of different situations. The technology can also be used to evaluate radon concentrations and WL measurements.

TL is the ability of certain materials, such as lithium fluoride, to retain certain changes in the electron energy distributions induced by absorption of radiation. A small but constant fraction of electrons of the electron-hole pairs created by the absorption of the radiation energy are trapped for extended periods of time by interstitial imperfections in the lattice structure. When the material is heated to a few hundred degrees centigrade by an external source, the electrons are driven from these traps and the subsequent recombination produces a visible light photon in the blue-green area of the electromagnetic spectrum (wavelength ~ 400 nm). These photons are multiplied by a photomultiplier tube or photodiode after the TL material is heated and a stream of photons produced. The charge produced by the photoreceptor is proportional to the radiation dose delivered to the TL material.

Thermoluminescent dosimeters (TLDs) record all radiation doses so the radon results must be corrected for background radiation. The TLDs are mounted in a detector assembly that filters the daughters from the ambient air then causes the daughters from the radon gas decay to attach to the surface of the TLD. The TLD, usually a rectangular chip of a few millimeters on a side, is removed from the detector assembly and placed in a separate reader where it is heated under controlled conditions and the light released measured.

In one detector configuration, the air entering the measurement chamber passes first through silica gel to remove the moisture then through a filter that removes the daughter products then into a funnel-shaped chamber. In the chamber, a battery-induced electrical field attracts the daughters to the surface of the TLD. The TLD is mounted at the narrow end of the funnel.

Occasionally a TLD is used in conjunction with another detector in a radon measurement device. One example is the personal radon monitor (PRM) described by Litt et al. The PRM is a sensitive, passive integrating device used to monitor individual human exposures. Radon diffuses into the monitor through a 4.8 mm thick conducting foam barrier that keeps out the progeny. The radon detector is a 9 $\times$ 9 mm CR-39 nuclear track film. Gamma ray exposure data are obtained from CaF$_2$ TLD chips placed beneath the CR-39. The CR-39 and CaF$_2$ TLD are covered with thin aluminized Mylar that nullifies any charge artifacts. Some attenuation of the alpha particle energies occurs in the Mylar; however, the Mylar is necessary to produce a uniform track distribution. Each PRM has provision for triplicate CR-39 film and TLD exposures. The PRM housing is a cylinder, 7.5 cm in diameter and 3.0 cm in height, and is worn on a belt.

### 3.2 Active Radon Detectors

#### 3.2.1 Scintillation Detectors

There are several basic types and configurations of scintillation detectors. The scintillation process begins when a fraction of the kinetic energy lost in the scintillator by the ionizing radiation is converted to light that is then observed by a photosensitive device such as a photomultiplier tube or a photodiode. This device generates an electrical pulse, quite small but usually proportional to the amount of light observed. Electrical amplifiers produce the much larger but still proportional signal that is counted and perhaps analyzed.

The scintillators and the photosensitive devices must be chosen so the maximum efficiency for observing the light is obtained. Usable scintillation light is usually produced in the blue-green wavelengths, around 400 nm, since most of the photosensitive devices are most efficient at those wavelengths.

Several different scintillation detectors can be used for radon measurements. Silver activated zinc sulfide [ZnS(Ag)], one of the earliest known scintillating substances, is used in powder form to coat the inside surface of measuring cells made of material transparent in the blue-green wavelengths of the visible spectrum. Radon-containing air is drawn into the cell, perhaps through a filter to remove the existing daughters. The cell can be sealed before counting or continuously pumped through the cell during counting. The vessel is placed in a dark, light-tight environment and observed by the photosensitive monitor. A significant fraction of the alphas...
produced by the decay of the radon and its daughters impinge on the ZnS; the resultant light flashes are seen and recorded. The more energetic betas may also be counted. The thin ZnS layer is effectively insensitive to gamma radiation. The system is calibrated with known activities of radon and the vessel volume is determined accurately. The cells, frequently referred to as Lucas cells, after the creator of the original cell, are available in many different cell volumes and configurations. The cell size is generally prescribed by the size of the active area of photomultiplier tube; the larger the volume, the lower the sensitivity and the LLD.

This system is used in several counting modes. A grab sample of filtered radon-containing air allowed to come to equilibrium (a four-hour delay before counting) is a very popular method for determining radon concentration. If only relative differences in radon concentrations are desired, a sample taken can be counted without delay in a “sniffer” type mode.

The most popular technique for determination of the WL is to collect the radon daughters on a high efficiency filter and then count the emitted alphas without discrimination (sorting by alpha energy) during or after the end of sampling. A number of different sampling and counting intervals can be used to determine the individual concentrations of $^{218}$Po, $^{214}$Pb and $^{214}$Bi. One very popular method for determining the WL, developed by Kusnezov and later refined by George, consists of a single gross alpha counting interval usually between 40 and 90 min after a 5–10-min sample period. The LLDs for $^{218}$Po, $^{214}$Pb, $^{214}$Bi, and the PAEC for a five-minute sample at a flow rate of 10 L min$^{-1}$ are 20 Bq m$^{-3}$ (5 pCi L$^{-1}$), 7 Bq m$^{-3}$, 20 Bq m$^{-3}$, and 50 nJ m$^{-3}$ (0.0025 WL) respectively.

One commercially available system is manufactured by the Pylon Electronic Development Co. The TEL 520 is a trace level radon gas detector. The sensor is a 14,000 mm$^2$ high efficiency ZnS(Ag) detector dimensionally optimized for 6.00–7.69 MeV alpha particles with an efficiency of approximately 4 cpm pCi$^{-1}$ coupled to a specially selected stable high-gain photomultiplier tube and unique scaler circuitry. It may be used with two filters to measure both radon and thoron concentrations.

One of the problems with these systems is that the radon and daughter products tend to be difficult to flush from the detector cells. Thus, the background counting level gradually increases as the cell is reused. Although the rate of increase can be reduced by flushing the cells with a radon-free gas the increasing background raises the LLD of the system lowering its sensitivity with continuous use of the cells.

Another commonly used scintillation material is NaI doped with an impurity (TI). This detector is most sensitive to gamma radiation and essentially insensitive to alphas and betas. The vessel used with this system is usually fabricated of material, such as aluminum or polyethylene, that has a low attenuation for the gammas and X-rays produced during the decay of radon and the daughters. With this system, the radon is pumped into the vessel and the vessel is placed in a specific physical orientation with respect to the photomultiplier tube assembly. The fraction of emitted gammas from the radon decay that pass through the detector may deposit some or all of their energy into the scintillation crystal. The resulting light flashes are counted and analyzed. NaI(Tl) detection systems are typically used to analyze the passive activated charcoal canister monitors for integrated radon concentration determinations.

This system is also sensitive to gammas from background radiation so it is usually housed with a substantial shield of lead or concrete to reduce the background interference. Although NaI(Tl) is the most efficient and most cost-effective material for this detector configuration, other scintillator materials such as CsI could be used.

Liquid scintillators are also useful for radon detection. They have the advantage of higher counting efficiency since the radon and the daughters are intimately mixed with the scintillator material. The disadvantages include the need for wet chemistry to prepare the samples and limitations due to the solubility of the cocktail solutions. Usually the radon-bearing air is passed through an organic solvent in which radon is highly soluble at low temperatures. The mixture is introduced into a vial containing a liquid scintillator. The vial is then sealed and placed in an optical cavity where the light flashes produced as each $^{222}$Rn decay are followed by two alpha particles and two beta particles, and are observed by a photosensitive detector and counted and perhaps analyzed. One technique, due to Van Dijk and De Jong,$^{12}$ used 4 g of silica gel (size distribution, 1–3 mm) cooled over liquid nitrogen to trap the radon. After absorption, the tube with silica gel was warmed in ice–water for 5 min, after which the contents were added to a counting vial containing 20 mL of a toluene-based scintillation liquid.

The use of liquid scintillation for analysis of activated charcoal passive monitors has been discussed in another section. Liquid scintillation may also be used to measure radon concentrations in water.

Kim$^{20}$ has investigated the use of fiber optic scintillation glass. They have developed a detector constructed of a bundle of cesium s doped glass fibers in a light-tight chamber. The radon-containing air is pumped into the chamber and diffuses into the fiber bundle. There the large effective surface area of the fiber bundle detects the alphas released with high efficiency.

### 3.2.2 Internal Gas Ionization Chamber Counters

In these systems, the radon and daughters are introduced into a chamber in which an electrical field has
been established between two electrodes. The radiation emitted in the decay process ionizes the air molecules, generating electrons and positively charged ions, which are drawn to respective electrodes in response to the Coulomb forces present. The resultant current can be measured as electrical pulses (for the alpha particles since the magnitude is large enough), averaged over a period as a current, or collected as a total charge for a period. Since the currents generated by the detector volumes are quite small, the measurement systems tend to be sophisticated and complex. From any of these parameters, the average radon activity in the active volume can be determined if the air sample is filtered or the WL if the ambient radon daughters are not filtered out and the ER is determined or assumed.

Ionization chambers are among the most accurate and sensitive methods for radon concentration measurements. They are also among the most expensive and complex. Thus, they are typically used as primary laboratory calibration instruments for radon measurements and for evaluating secondary instruments for traceability purposes. A typical LLD for these instruments is about 0.7 mBq (0.019 pCi) for a 17-hour count.

barrier detectors, a slightly different configuration, are also used, as are photodiodes.

The instruments usually employ an onboard computer for the analysis and data storage as well as to perform the measurements on a preset schedule. They are frequently used as sniffers. One device, developed by the US Department of Energy Environmental Measurements Laboratory (EML), has a sensitive volume of 6 L. Air is drawn into the cylindrical volume and the charged daughters are attracted to the surface of the detector for spectroscopic analysis. The system can measure 150 Bq m$^{-3}$ of $^{222}$Rn or $^{220}$Rn in less than 10 min and stores the data, along with the temperature and the relative humidity measurements, in the computer. The energy discrimination capabilities of the detector allow the device to measure the short-lived $^{218}$Po in a sniffing mode since it can respond to concentration changes in a short time. The sensitivity for $^{218}$Po is 0.08 cpm Bq$^{-1}$ m$^{-3}$ (3 cpm pCi$^{-1}$ L$^{-1}$).

WL measurements are made by drawing air through a filter detector assembly. The alpha emissions from radon and thoron daughters are measured and the data is stored on an onboard computer. One portable, battery-operated device has a small internal pump with a flow rate around 0.15 L min$^{-1}$. The computer-scheduled sampling program is typically one hour sampling intervals over periods that can range from one to seven days. The LLD is about 0.0005 WL. This unit has a separate computer-based reader and programmer.

Table 2 summarizes the instruments and methods for the estimation of $^{222}$Rn concentrations.$^{(2)}$

### 4 COMPARISON STUDIES AMONG THE RADON, INDOOR AND REMOTE MONITORS

Several comparison studies of the different types of detectors and measurement techniques have been published. Martz et al.$^{(13)}$ found the correlation coefficient of 0.9980 (and a linear slope of 1.052) between one type of alpha track monitor results and diffusion barrier charcoal canister (DBCC) results, averaged over a six-month period. The correlation coefficient between the 60 paired 1-wk DBCC measurements and the integrated Pylon AB-5 continuous scintillation chamber measurements is 0.9879 and the slope is 1.05.

Future comparison studies should be made among the TLD and solid state nuclear track detector (SSNTD) radon and RDPs measuring devices that would include Kottrappa et al.$^{(14)}$

An international climatic test program for integrating radon detectors is described in the paper authored in 1990 by Colle et al.$^{(16)}$ It suggested upgrading, expanding and replacing the primary radon measurement system, consisting of pulse ionization chambers and ancillary gas handling and gas purification equipment. A secondary measuring system$^{(17)}$ for $^{222}$Rn-in-air, based on measurements of the photon emission rate of radon samples contained in spherical 35-mL glass ampoules with a NaI(Tl) well counter, was calibrated against the NISTp$^{(21)}$ pulse-ionization-chamber national radon measuring system with an overall uncertainty of approximately 2%.$^{(17)}$

An international intercomparison of marine atmospheric $^{222}$Rn measurements in Bermuda was done in October 1991.$^{(22–24)}$ NIST polyethylene-encapsulated $^{226}$Ra/$^{222}$Rn emanation standards were used for calibration of electret-based integral radon monitors.$^{(25)}$

### ABBREVIATIONS AND ACRONYMS

- **DBCC**: Diffusion Barrier Charcoal Canister
- **EEC**: Equilibrium Equivalent Concentration
- **EML**: Environmental Measurements Laboratory
- **ER**: Equilibrium Ratio
- **LLD**: Lower Limit of Detection
- **NCRP**: National Council on Radiation Protection
- **NIST**: National Institute of Standards and Technology
- **PAEC**: Potential Alpha Energy Concentration
- **PRM**: Personal Radon Monitor
- **RDP**: Radon Daughter Product
- **SSNTD**: Solid State Nuclear Track Detector
- **TL**: Thermoluminescent
- **TLD**: Thermoluminescent Dosimeter
- **USEPA**: United States Environmental Protection Agency
- **WL**: Working Level
- **WLM**: Working Level Month

Solid-phase microextraction (SPME) is a modern sampling/sample preparation method, used for isolation and preconcentration of organic molecules from a variety of matrices. SPME uses a short piece of a fused silica fiber coated with a polymeric stationary phase. The fiber is mounted in a device resembling a syringe. During transport, storage and manipulation, the fiber is retracted into the needle of the device. During extraction and desorption of the analytes, the fiber is exposed. Analytes present in a sample partition into or onto the coating, depending on its type. The process continues until equilibrium is reached between the coating and the sample. From then on, longer extraction times do not result in larger amounts of analyte extracted. Once the extraction is finished, the fiber is retracted back into the needle, and the device is transferred to a gas or liquid chromatograph for analyte separation and determination. When gas chromatography (GC) is used, the analytes are thermally desorbed from the fiber in a GC injector. Coupling of SPME with high-performance liquid chromatography (HPLC) requires a special interface.

Two distinct SPME coating types are available commercially. Coatings of the first type, including poly(dimethylsiloxane) (PDMS) and poly(acrylate) (PA), extract analytes by absorption. This process is non-competitive, therefore in most cases the amount of an analyte extracted by such coatings from a sample is independent of the matrix composition. No saturation or displacement effects occur. The amount of an analyte extracted from a sample is linearly dependent on its initial concentration, provided that several important variables, including (but not limited to) temperature, extraction time and mass transfer conditions, are kept constant. Coatings of this type usually perform very well for compounds of medium to low volatility.

Coatings of the second type, including poly(dimethylsiloxane)/divinylbenzene (PDMS/DVB), Carbowax™/divinylbenzene (CW/DVB) and Carboxen™/poly(dimethylsiloxane) (CX/PDMS), extract analytes by adsorption. This process is limited to the surface of the coating. It is competitive, which means that a molecule with higher affinity to the coating can displace a molecule with lower affinity. Since the number of active sites on the surface of any coating is limited, a linear response for those coatings can be expected only when the concentrations of all the compounds that can be extracted by the coating from a sample are low. Adsorption-type coatings are particularly suitable for volatile analytes, for which they offer much better sensitivity than PDMS or PA.

SPME is very well suited for field applications, especially when the analysis is carried out on site. The fiber can be exposed directly to the medium analyzed, for example lake water or ambient air, without the need to collect a sample and without knowing the exact volume of the sample the fiber is exposed to. Analysis can then be performed using field portable instrumentation. Manual operation of the device is very simple. The fibers are reusable, which makes the cost of analysis low. Separation of volatile components sampled by SPME can be very fast when a dedicated system (available commercially from SRI Instruments) is used.

Alternatively, SPME can be used to sample in the field, and then transported for the analysis to the laboratory. Modified devices have to be used for this purpose to avoid analyte losses during transport and storage, as well as contamination of the samples. Transporting fibers is much easier than transporting glass or metal containers with water or air samples.

The main disadvantage of SPME in the field is its lack of robustness. The needle can be easily bent, and the fiber can be broken when handled without sufficient care.
New designs of field portable SPME devices address those issues. Also, it might be difficult to accurately control in the field all the experimental parameters that affect the amount of analyte extracted.

1 INTRODUCTION

Field analysis is rapidly gaining more and more importance, responding to the need for immediate results in environmental monitoring, as reviewed by V. Lopez-Avila et al. Immediation remediation for industrial spillages or environmental accidents is possible only if the results are provided in real time. Performing an interactive sampling, where only relevant locations are sampled, can save time and resources. Also, the costs of a field investigation are lower compared to a traditional procedure, by cutting the expenses of transport and storage of bulky and heavy environmental samples, by shortening the time of the entire analysis and by focusing the investigation only on significant sampling sites. Results are more representative of the real sample composition if the analysis is performed directly in the field, so that volatile losses or sample degradation are minimized.

To date, several types of analytical instrumentation can be transported to the field for on-site investigations. The promise of cheaper and faster analysis is pushing the optimization of field analytical methods, from immunochemical assays and chemical sensors to GC. Even the sensitivity and identification capabilities of mass spectrometry (MS) can be applied directly in the field with the recent introduction of portable instruments.

For field investigations of volatile compounds, portable gas chromatographs can be utilized. Fast GC, which utilizes short capillary columns and high carrier gas flow-rate, can reduce the time of the instrumental analysis by one order of magnitude, producing therefore even more immediate results and reducing the cost of analysis.

SPME is a powerful tool for the extraction/sample preparation of environmental samples, widely described in literature. A microextraction, defined as extraction of a very small portion of analytes, is performed by a polymeric coating immobilized on a silica fiber and exposed to the sample. For this purpose, the fiber is mounted at the end of a small diameter stainless steel tube, which, in turn, is located inside a fine steel needle. The fiber can be retracted into the needle or exposed from it by manipulating the plunger of a syringe-like device. When the fiber does not need to be exposed, it can be protected inside the needle. The device is commercially available from Supelco (Bellefonte, PA), together with a variety of fiber assemblies with different coatings.

The SPME extraction process is based on partitioning of an analyte between the sample matrix (gas, liquid or solid) and the fiber. Typically, only a fraction of the total amount of the analyte present in the sample is extracted. Exhaustive or near-exhaustive extraction can be achieved only under specific conditions, when the volume of the sample is small and the affinity of the compound towards the coating (measured by the fiber/sample partition coefficient \( K_{fA} \)) is high. The amount of an analyte \( n \) extracted by absorption-type SPME fibers at equilibrium in a two-phase system can be described by Equation (1):

\[
  n = \frac{K_{fA} V_f V_f C_0}{V_s + K_{fA} V_f} 
\]

where \( V_f \) is the fiber coating volume, \( V_s \) is the sample volume, and \( C_0 \) is the initial concentration of the analyte of interest in the sample. This equation indicates that in a two-phase system there is a direct relationship between the initial analyte concentration in the sample and the amount extracted, even though other factors influence the efficiency of extraction at equilibrium, such as the affinity of the fiber for the target compound, and the sample volume. As in all equilibrium processes, several factors can affect the amount of an analyte extracted by the fiber, from the temperature and the pH to the organic and salt content in the sample.

If an adsorption process is applied for extraction, a different theory is necessary to describe the extraction process. The following considerations pertain to PDMS/DVB, CW/DVB and Carbowax™/template resin coatings. No comprehensive theory has been developed yet for the CX coating, for which capillary condensation plays an important role.

Based on Langmuir’s theory of the adsorption process, Equation (2) can be used to describe the processes involved in SPME extraction with solid coatings:

\[
  n = C_{fA} V_f = \frac{K_A C_{0A} V_s V_f (C_{fA}^{\text{max}} - C_{fA}^{\infty})}{V_s + K_A V_f (C_{fA}^{\text{max}} - C_{fA}^{\infty})} 
\]

where \( n \) is the amount of analyte adsorbed by the porous polymeric coating at equilibrium,

\[
  C_{fA}^{\infty} \quad \text{is the concentration of analyte A on the fiber at steady state;} \\
  V_f \quad \text{is the volume of the fiber coating;} \\
  K_A \quad \text{is the adsorption equilibrium constant of analyte A;} \\
  C_{0A} \quad \text{is the initial concentration of analyte A in the sample;} \\
  V_s, V_f \quad \text{are the volumes of the sample and of the fiber, respectively;} \\
  \]
C_{f,max} is the concentration of active sites on the surface (corresponding to the maximum achievable analyte concentration on the surface).

The general form of Equation (2) is very similar to that of Equation (1), which describes the extraction process in a two-phase system when absorption is the extraction mechanism. The main difference between Equations (1) and (2) is the presence of the fiber concentration term \((C_{f,max} - C_{f_A})\) in the numerator and denominator of Equation (2) (also, note that the meaning of \(K_{A}\) is entirely different than that of \(K_f\); \(K_A\) is adsorption equilibrium constant, while \(K_f\) is the partition coefficient). For very low analyte concentrations on the fiber, it can be assumed that \(C_{f,max} \gg C_{f_A}\). For this condition to be fulfilled, analyte concentration in the sample and/or its affinity towards the coating must be very low. When these requirement(s) are met, a linear dependence should be observed. If, however, the amount of an analyte on the fiber is not negligible compared to the total number of active sites, the dependence cannot be linear any more.\(^{(6)}\)

SPME fibers can be exposed to solid, liquid or gaseous matrices, using three different extraction modes:

- direct immersion of the fiber in the sample matrix (liquid or gaseous matrices);
- extraction of the headspace above the sample (liquid or solid samples);
- direct immersion with the fiber protected with a high-molecular-weight cutoff membrane eliminating adverse effects when the sample is very dirty (liquid samples).\(^{(13)}\)

A variety of available polymeric coatings with different chemical properties allow the technique to be used for a broad range of compounds widely differing in polarity and volatility (from amines and phenols to volatile organic compounds (VOCs) and inorganic substances).\(^{(7)}\) To date, hundreds of applications have been developed with SPME,\(^{(8)}\) even though the power of this technique in areas including industrial hygiene and environmental and process monitoring has not been completely explored yet.

**1.1 Suitability of Solid-phase Microextraction for Field Analysis**

Several features of SPME make this technique very well suited for field investigations. The feature that differentiates SPME from all the other sampling techniques can be explained from the principle of the extraction-partitioning process described by Equation (1). If a large volume sample is extracted, e.g. atmospheric air or lake water, or \(K_f\) is very small (low affinity of the fiber coating toward the analyte), the term \(V_f\) in the denominator of Equation (1) is much larger than the \(K_f V_f\) term, and the latter can be neglected. The final relationship that describes the amount absorbed by the SPME fiber in such a case is described by Equation (3):

\[
n = K_f V_f C_0
\]

It follows from Equation (3) that under such conditions the amount of analyte extracted by the fiber at equilibrium, in a two-phase system, is not dependent on the sample volume. This means that collection of a known volume of a sample is not necessary in the sampling procedure, and the fiber can be exposed directly to the sample in the field, without removing it from the environment. The amount of analyte extracted is negligible in comparison to the total amount present in a large volume of a sample. The system is not disturbed by the SPME extraction. For instance, the scents released by a flower can be sampled by simply exposing the fiber to the inside of the flower bulb without removing it from the field, and a real field sample can be analyzed. The above is not always true: if the amount of scents removed from the headspace of the flower is not negligible, the flower will react by increasing their production and the normal situation will be disturbed.

Other features make SPME very suitable for field use. It is pen-shaped, easy to handle and to operate by any operator. It can be exposed even to locations difficult to reach for sample collection (e.g. groundwater or deep soil). It is reusable and the fiber can be easily changed. If a field portable instrument is available, the fiber can be immediately desorbed in the hot injector of a GC for chromatographic investigation, since the extraction and sample preparation processes are combined into a single step. SPME can also be coupled to fast GC: the lack of solvent in the whole process is an important requirement for high-speed GC.\(^{(9,10)}\)

The possibility of automation of the extraction technique makes it potentially useful for semi-continuous monitoring of industrial processes\(^{(11)}\) and for industrial hygiene purposes.\(^{(12)}\)

The advantages of SPME for field sampling can also be exploited when the use of portable instrumentation is not possible. After field sampling, the SPME device, with the analytes stored on the fiber, can be transported to the laboratory for further investigation. A special sampler is required for this purpose in order to prevent analyte losses during storage and transportation. Since the SPME fiber is fragile, care should taken during sampling in field conditions. New SPME field samplers were designed in order to satisfy all the features required by field applications, such as robustness of the device, protection of the fiber during sampling and minimization of analyte losses during storage.
2 SOLID-PHASE MICROEXTRACTION COUPLED TO FIELD PORTABLE FAST GAS CHROMATOGRAPHY

High-speed GC is a powerful analytical technique that dramatically reduces the time of chromatographic separation, by up to one order of magnitude. Fast GC typically utilizes short narrow-bore capillary columns and high carrier-gas flow rates. Good separation can be achieved by fast GC if narrow injection bands are produced. Band broadening can be minimized by avoiding the use of solvents, by reducing the detector inner volume and by introducing the sample to the column very rapidly.

SPME coupled to fast GC is a good combination to perform rapid and cost-effective investigations in the field, even of complex organic samples. SPME is particularly suited for fast GC, as it is solvent-free, and the thin coatings can provide very fast desorption of analytes at high temperatures. Some instrumental modifications were performed recently in order to achieve successful fast separations.

Figure 1 Dedicated injector to couple SPME with fast GC, allowing heating rates of up to 4000 °C s⁻¹. 1: modified Swagelok fitting; 2: stainless steel tubing; 3: molded septum; 4: nut; 5: needle guide; 6: nut; 7: drilled-thru plug; 8: stainless steel tubing; 9: 0.53-mm i.d. fused silica capillary; 10: electrical contact.

A portable system was optimized for field investigations using SPME coupled to fast GC and was commercialized by SRI Instruments (model 8610C, SRI Instruments, Torrance, CA). The instrument was tested in combination with a flame ionization detector (FID), a photoionization detector (PID), and a dry electrolytic conductivity detector (DELCID). A dedicated injector, presented in Figure 1, was mounted on the portable system in order to use SPME for high-speed separation. The injector guarantees very fast thermal desorption of the analytes from the SPME fiber.

The injector for high-speed GC should produce as narrow an injection band as possible. Regular injector ports have too large internal volumes (e.g. split/splitless injector), since they usually have to accommodate large volumes of gaseous samples or vapors produced by solvent injection. Thermal focusing for separation improvement is not convenient for fast separations, since temperature programming is impractical for high-speed GC. Hence, an injector port with a small internal volume was required for this application. Also, very fast thermal desorption from the SPME fiber was required to produce a narrow injection band and achieve effective separation. In the dedicated injector for SPME coupled to fast GC, the injector port was maintained cold during needle introduction and was rapidly heated only when the fiber was exposed to the carrier gas stream. The desorption area of the injector was heated by capacitive discharge that allowed heating rates as fast as 4000 °C s⁻¹, and very narrow injection bands were observed, as required by fast GC. The injector (Figure 1) was based on a modified Swagelok fitting (1) which was drilled through in the middle, and the carrier gas was supplied by a piece of 1/16 inch tubing (2), soldered to it. The inlet of the injector was closed with a molded septum (3) and the original SRI nut with needle guide (4). The hole inside the fitting was enlarged to accommodate the brass needle guide (5). The back end of the injector was closed with a nut (6) and drilled-thru plug (7). The plug had a piece of gauge 19 steel tubing (8) soldered into it. Inside the tubing was a segment of 0.53 mm i.d. fused silica capillary (9). The tubing (8) assured mechanical stability and durability, and served as the heating element at the same time. The capacitative discharge power supply was connected to the injector body and to the end of tubing (8) through contact (10). The GC column was connected to the injector with a zero-dead volume butt connector. Tubing (8) was thermally insulated along its entire length (not shown).

Neither the FID nor the DELCD detector required any modifications before being used for fast GC. On the other hand, the relatively large internal volume of the PID caused a very significant peak broadening. To overcome this problem, a simple insert was designed and introduced into the internal cavity of the detector, reducing the
internal volume of the PID from approximately 130 µL to 25 µL. The insert was tightly fitted into the detector cavity to avoid creation of void volumes. An excellent improvement in resolution for separation of BTEX (benzene, toluene, ethylbenzene, xylene) was achieved in this way.\textsuperscript{(13)}

The system was optimized in the laboratory with standards of BTEX (benzene, toluene, ethylbenzene and \( o,m,p \)-xylene; 200 µg L\(^{-1} \)) each compound in water) and a complete separation was performed within 15 s. Purge-ables A (trichlorofluoromethane, 1,1-dichloroethylene, dichloromethane, 1,1-dichloroethane, trichloromethane, trichloroethene, 1,2-dichloropropane, 2-chloroethyl vinyl ether, 1,1,2-trichloroethane, tetrachloroethene, dibromochloromethane, chlorobenzene; 200 µg L\(^{-1} \)) each compound in water) were separated in 2 minutes with good precision using the DELCD.\textsuperscript{(9,10)}

The SRI system was then carried to the field for trace analysis of trichloroethylene (TCE) in soil (see section 3.1) and airborne formaldehyde for industrial hygiene monitoring (see section 3.2).

### 3 SELECTED FIELD APPLICATIONS OF SOLID-PHASE MICROEXTRACTION

#### 3.1 Field Analysis by Solid-phase Microextraction Coupled to Gas Chromatography

Several applications of SPME and high-speed GC for field analysis have been reported. The portable SRI model 9300B instrument, described in the previous section and now commercially available as model 8610C, was applied in the field for various matrices and different pollutants: field determination of traces of TCE in soil samples,\textsuperscript{(13)} VOC in groundwater,\textsuperscript{(14)} and indoor measurements of airborne formaldehyde\textsuperscript{(15)} (see section 3.2).

SPME/fast GC field determinations were performed by quantifying TCE in soil (clay) samples. By collecting core samples from depths up to 5 m, the migration of the pollutant was investigated. Soil samples were collected and extracted with methanol. An aliquot of the extract obtained was used to spike pure water, and the aqueous solution was then vigorously stirred in a sealed vial to equilibrate with the headspace above the water. A PDMS/DVB 65 µm SPME fiber was exposed to the headspace of the static water sample for the extraction. The described procedure was performed directly in the field. After extraction, the SPME fiber was desorbed in the portable fast GC coupled to PID system for on-site instrumental investigation. The entire process of SPME extraction of spiked water samples, desorption and instrumental analysis took 3 min to complete, allowing over 500 samples to be quantified in 10 days. This successful study is an effective application of SPME coupled to fast GC for rapid field investigations.

Groundwater samples were analyzed by SPME/fast GC in the field to evaluate VOC content.\textsuperscript{(14)} The commercially available instrumentation (SRI model 8610C) was used for this purpose. Of great interest is the validation performed by comparison with traditional liquid--liquid extraction (LLE) followed by instrumental analysis by gas chromatography/electron capture detector (GC/ECD) with a Hewlett Packard model HP 5890 GC in the laboratory. A comparison of the quantitative results obtained by the two methods showed a scattered difference between 3% and 5%, demonstrating the reliability of field investigations performed by SPME/high-speed GC.

#### 3.2 Field Applications for Indoor Air Monitoring

Monitoring of air is becoming more and more important not only for environmental pollution evaluations, but also for industrial hygiene applications.\textsuperscript{(12)} SPME can be a useful tool for industrial hygiene studies since it is suitable for field evaluations and is easy to automate. It can potentially be used therefore for semi-continuous monitoring of indoor/outdoor air pollutant levels. An automated procedure is necessary to monitor levels of hazardous and undesirable exposures workers are subjected to in their working day. Proper monitoring equipment for this purpose should be portable, should give immediate and continuous results and should alert to excessive exposure.\textsuperscript{(12)}

When sampling air, SPME can be used in two ways. In the conventional approach, the fiber is simply exposed to the atmosphere analyzed by depressing the plunger of the SPME device. The analytes reach the fiber coating mainly via advection and (to a lesser extent) diffusion. The fiber is usually exposed for a time long enough for the analytes to reach equilibrium. Analyte equilibration times depend on their partition coefficients and mass transfer conditions. Alternatively, SPME can be used as a time-weighted average (TWA) sampler for gas phase analytes. In this approach, the fiber is retracted a known distance into the needle during the sampling period. In contrast to the conventional approach, the analytes are not allowed to reach equilibrium with the fiber. Analyte sampling rate is controlled by a number of factors, including the diffusion coefficient and the concentration gradient inside the needle. Analysis by this method yields the concentration of an analyte averaged over the entire sampling period (e.g. eight hours in industrial hygiene).

TWA concentration is defined according to Equation (4):

\[
\overline{C}_{\text{tn}} = \frac{C_1t_1 + C_2t_2 + C_3t_3 + \cdots + C_nt_n}{t_1 + t_2 + t_3 + \cdots + t_n}
\]  

(4)
where \( \overline{C_{ta}} \) is the TWA concentration, \( C_1 \) is the analyte concentration observed for time \( t_1 \), and so on, until time \( t_n \). This definition can be used to determine TWA concentration from discrete measurements (grab sampling). Such measurements should cover the entire period of interest. Conventional SPME can be relatively easily utilized for this type of measurement provided field portable instrumentation is used. The fiber has to be exposed to the outside atmosphere and equilibrated with the analytes, followed by immediate desorption and GC analysis. Once the analytes are removed from the fiber, the entire cycle has to be repeated for as many times as required to cover the period of interest.

An alternative approach to determining TWA concentration is with one sampling session where \( t_1 = t_n \). For this approach to be successful, one has to make sure that the amount of analyte reaching the trapping medium at any given moment is directly proportional to the analyte concentration outside of the sampler at the same moment. It is also very important that analyte molecules trapped inside the sampler are not re-released to the surrounding atmosphere and do not affect further uptake of analyte molecules. When the latter conditions are fulfilled, the trapping medium is called a “zero sink”.\(^{(16,17,18)}\)

The following presentation is based on a paper by Martos and Pawliszyn.\(^{(19)}\) TWA sampling by SPME can be accomplished by leaving the fiber inside the needle during the sampling session. Figure 2(a) shows the SPME fiber position for TWA sampling, while Figure 2(b) presents analyte concentration gradient inside the needle. In Figure 2, \( C_{\text{BULK}} \) is the analyte concentration in the bulk of the atmosphere examined, \( C_{\text{FACE}} \) is the concentration at the face of the sampling device, and \( C_{\text{SORBENT}} \) is the concentration at the gas/sorbent interface.

Since the dimensions of the SPME needle are very small, analytes can reach the fiber only by diffusion. From Fick’s law, analyte transport in such a system can be described by Equation (5):

\[
\frac{dJ}{dt} = -\frac{DA}{L} dc
\]  

(5)

where \( J \) is the weight (ng) of analyte passing through a cross-section \( A \) (cm\(^2\)) during a time \( t \) (min); \( D \) is analyte diffusion coefficient in air (cm\(^2\) min\(^{-1}\)), \( L \) is the diffusion path length (cm), and \( C \) is analyte concentration (ng cm\(^{-3}\)). We can now define the sampling rate \( R \) (cm\(^3\) min\(^{-1}\)) by Equation (6):

\[
R = D \left( \frac{A}{L} \right)
\]  

(6)

Hence (Equation 7)

\[
\frac{dJ}{dt} = -R dc
\]  

(7)

Equation (7) can be integrated with the following limits to concentration and time to give Equation (8):

\[
J = -R \int_{t_1}^{t_2} C_f \, dc = -R t \frac{C_f}{C_s} \int_{t_1}^{t_2} \frac{dc}{C_f} \]  

(8)

where \( C_f = C_{\text{FACE}} \), and \( C_s = C_{\text{SORBENT}} \). After integration, Equation (9) is obtained:

\[
\frac{J}{t} = R(C_f - C_s)
\]  

(9)

where \( J/t \) is the average sampling rate over the period of time from \( t_1 \) to \( t_2 \). For a zero sink, \( C_s = 0 \), and \( J = M \) (mass of analyte trapped by the coating), so that Equation (10) has the following form:

\[
\frac{M}{t} = R \cdot \overline{C_f}
\]  

(10)

where \( \overline{C_f} \) is the average concentration of an analyte at the face of the SPME needle during the sampling period. It follows from the above equation that the rate of analyte uptake is directly proportional to the sampling rate (being a function of the geometric dimensions of the sampler and analyte diffusion coefficient) and analyte concentration.

Equation (10) can be rearranged to allow the determination of TWA concentration \( \overline{C_{ta}} \) of an analyte from the mass of the analyte extracted by the SPME fiber.
Sampling rate $R$ can be easily determined by exposing the SPME device with the fiber retracted into the needle to an atmosphere containing a constant concentration of the analyte of interest. In such a case, from Equation (9) we can derive Equation (12):

$$R = \frac{M}{tC_F}$$  \hspace{1cm} (12)

Once $R$ is known, TWA concentration of an analyte in air can be easily determined by SPME from the amount of analyte extracted by the retracted fiber in a given time $t$.

SPME fiber assembly is very flexible as a passive sampler, since the length of the diffusion path $L$ can be easily changed by repositioning the fiber inside the needle. When high concentrations of an analyte are to be analyzed for prolonged periods of time, the fiber can be retracted deeper into the needle, and vice versa. If the sampling rate $R$ is determined with the fiber at $L$ and the sampling took place with the fiber at $L'$, the left side of Equation (10) has to be multiplied by a factor $L'/L$ to obtain correct results.

The assumption that SPME coating acts as a zero sink is not always fulfilled. Analytes with relatively low affinity to the coating may reveal certain non-negligible vapor pressure at the gas–coating interface, according to Equation (13):

$$C_S = X_A \frac{P^*MW}{P_t} \frac{298}{24.45\ T}$$  \hspace{1cm} (13)

where $X_A$ is the mole fraction of analyte in the PDMS coating, $P^*$ is the pure analyte vapor pressure, $P_t$ is the total gas pressure at the interface, $MW$ is the analyte molecular weight, $T$ is the temperature in Kelvin and 24.45 is the molar volume of gas at 298K. When $C_S \neq 0$, a reduction in the concentration gradient occurs, as depicted by the dotted line in Figure 2(b). The zero sink assumption is usually fulfilled for highly efficient sorbent materials and for chemisorption, as is the case with on-fiber analyte derivatization.

Figure 3 presents the results of an experiment in which continuous exposure of the SPME fiber assembly with retracted needle for a certain time to a standard gas atmosphere was compared to intermittent exposure, in which the fiber assembly was alternately exposed to the standard gas and pure air. In the latter case, the total time for which the assembly was exposed to the standard gas was equal to the continuous exposure time. Should the zero sink assumption be fulfilled, the amount of analyte from the intermittent exposure should be the same as from continuous exposure. It follows from Figure 3 that
PDMS coating does not act as a zero sink for analytes with relatively low affinity to this coating. Assuming that a 10% loss is acceptable, the useful range starts with compounds characterized by fiber/gas partition coefficients \( K_{fg} \) greater than 1000. Short-term (~30 min) TWA sampling is possible for such compounds.

Figure 3 also presents what fraction of equilibrium amount was loaded on the fiber after 15 min continuous retracted fiber exposure. The data indicate that when the amount extracted is greater than ~5% of the equilibrium amount, analyte mass uptake rate becomes significantly affected. With this in mind, it is possible to use this method to sample n-undecane for 75 min with \( L = 0.3 \text{ cm} \), and proportionally longer with larger \( L \).

Applicability of this method for field use was proven in a study where styrene \( (K_{fg} \approx 3100) \) was determined in an industrial facility. The fiber was retracted 3 mm into the needle, and the sampling time was 30 min. The results were compared to those obtained using 30 min charcoal tube samples. Concentrations of 54 \( \mu \text{g L}^{-1} \) (25 °C) versus 56 \( \mu \text{g L}^{-1} \) (25 °C) were determined for the charcoal tubes and SPME, respectively.\(^{[15]}\)

PDMS coating is not an ideal sorbent for passive sampling of volatile and/or polar analytes. Sorbent capacity for such compounds is low, and the non-zero analyte vapor pressure at the surface of the coating affects the mass uptake rate. One way to remediate problems of this nature is to derivatize the analyte on the coating to a stable product with low vapor pressure and high affinity to the coating. Such an approach was verified with on-fiber derivatization of formaldehyde using o-(2,3,4,5,6-pentafluorobenzyl) hydroxylamine (PFBHA) with the PDMS/DVB fiber in the retracted position.\(^{[20]}\) Experiments in which the fiber doped with PFBHA was alternately exposed to a standard formaldehyde gas mixture and pure air indicated that a cumulative amount of the derivatization product (oxime) was formed with no measurable losses caused by intermittent exposure to pure air. Thus, the system fulfilled the ‘zero sink’ criteria. No significant losses of derivatizing agent were observed when the doped fiber was stored inside the needle of the SPME device, whose tip was inside an empty 1.8 ml vial sealed with a Teflon-lined septum during transportation to the field. After sampling, the fibers were carried to the laboratory for instrumental analysis. In another experiment, the doped fiber was exposed to a standard mixture containing 636 ppbv formaldehyde for 1007 min \( (L = 3.0 \text{ cm}) \). TWA concentration found with this system was within 7% of the expected concentration.

The device was tested in the field against the standard of the National Institute for Occupational Safety and Health (NIOSH) Method 2541. The fiber was retracted to 3.0 cm, and the sampling time was 420 min. Sampling was carried out in three separate locations. The TWA concentrations found for the SPME sampler were 109, 152 and 57 ppbv, compared to 102, 160 and 51 ppbv, respectively, for the reference method. The excellent agreement between the results obtained by the two methods indicates that passive sampling of formaldehyde using SPME can be a very successful alternative to currently used techniques, as it offers a number of unique advantages: the devices are small, lightweight, reusable and cheap, and the manipulations are minimal and very simple. Once the sampling is finished, the results can be obtained within minutes by thermally desorbing the derivatization product in a portable GC injector for chromatographic analysis.

On-fiber derivatization combined with portable fast-GC, previously described in section 3.1, can also be used for grab sampling of formaldehyde. In this case, the fiber is directly exposed to the atmosphere examined for sampling. The sampling time is selected according to formaldehyde concentration in the air. Very short sampling times (a few seconds) are used for high concentrations. When the expected formaldehyde concentration is low, the sampling time can be extended to a few minutes. In general, the sampling time is selected in such a way that the amount of analyte trapped is within the linear part of the uptake curve.

Grab sampling was carried out simultaneously with TWA measurements described above. The doped fiber was exposed for 30 s to the air and then immediately desorbed in the GC port. The entire procedure of fiber loading/sampling/sample preparation/separation and detection took 3 min with the portable system. Formaldehyde concentrations found in the same locations were 106, 140 and 93 ppbv, respectively. The agreement with the results of TWA sampling was therefore excellent, taking into account the completely different nature of the two types of measurements: grab sampling reflects concentrations averaged over a long period of time. The limit of detection for the grab sampling method was of the order of 10 ppbv (30 s sampling), which is well below the limits of detection of other formaldehyde grab sampling methods.

### 3.3 In Situ Analysis of Groundwater and Soil Gas

Volatile content in groundwater and soil should be measured on-site, because composition changes can occur during sampling, pumping or excavation. SPME can be successfully applied to monitor underground pollution as an alternative to other methods that showed some limitations in field applications.\(^{[21]}\) A device designed for this purpose (Figure 4) was developed by Nilsson et al.\(^{[21]}\) and tested in the field for the determination of VOCs in
groundwater and soil gases. The SPME sampling probe was introduced into the well, to reach groundwater for direct sampling. Monitoring of groundwater headspace or underground gases at different depths was accomplished by placing the SPME sampler at different depths, or over the headspace of the water. After extraction by exposure of the fiber, the probe was retracted to the surface and the SPME fiber was immediately desorbed in the GC of a mobile laboratory. Results obtained by underground sampling with the SPME probe were compared to concentrations found for the same samples collected with traditional procedures and analyzed by SPME in a mobile laboratory. VOC levels were evaluated in the underground waters of several wells. The results provided by in situ SPME extraction of groundwater were, in general, higher than those obtained with traditional sampling methods, where the pumping of the sample to the surface causes volatile compound losses. Toluene and naphthalene were detected by underground soil gas investigation and their presence was confirmed by extracting the same samples with Tenax tubes. To sample the volatile content of the soil, during excavation, an alternative SPME probe was designed to fit directly inside the head of a cone penetrometer. In this application of SPME, different ground levels can be monitored.

### 4 NEW ADVANCES IN SOLID-PHASE MICROEXTRACTION FIELD SAMPLERS

If a portable instrument is available, the SPME fiber can be immediately desorbed after sampling in the GC injector, and storage of the sample on the fiber is not necessary. If the instrument is not movable to the field, the sample has to be carried to the laboratory. Collection and transportation of bulky and/or heavy samples of water, soil or air can be avoided by using SPME for field extractions. The fiber can be exposed to the matrix directly where the sample is located, and only the SPME sampler, with the fiber sealed in an appropriate way, has to be transported to the laboratory. In this case the minimization of sample losses from the SPME fiber is crucial for the reliability of the results. A dedicated SPME sampler for field applications has to be designed to preserve the integrity of the sample during the transportation between the sampling location and the laboratory. The purpose of a recent study on the optimization of SPME field samplers was to achieve no losses during storage, even of volatile compounds, adsorbed/absorbed onto the SPME fiber by the time the sample is analyzed. An SPME device for field sampling should also be simple, easy to handle and to transport, robust, inexpensive and, in some cases, disposable, in order to avoid any cross-contamination due to multiple extractions of dirty matrices. It is important that the fiber is protected during the sampling procedure, so that it does not break when it is exposed to the matrix in field.

To date, several approaches have been studied to prevent analyte losses from the SPME fiber during storage. Various silicone rubber septa were tested as sealing materials for the needle during storage in the SPME sampler. By sealing the tip of the needle, the fiber was supposed to be stored in a closed environment. However, this method did not take into consideration the possible partitioning of the analytes released from the fiber during storage into the septum itself. Taking into account that a septum is made of nearly the same material as the PDMS fiber, the significance of such a
phenomenon should not be underestimated, especially for volatile analytes. Also, losses due to permeation of volatiles through the septum are possible. A field SPME sampler, commercialized by Supelco, is presented in Figure 5. The fiber is exposed to the sample by pushing the plunger (1) of the device during the extraction process, as presented in Figure 5(a). Sealing the device for sample storage is achieved by retracting the tip of the needle (3) into the sealing septum (5) (Thermogreen Septum LB-2, Supelco) placed in the aluminum nosepiece (2) of the device (Figure 5b). In this way, the SPME fiber (4), carrying the analytes, is stored inside the sealed needle. The lifetime of this device is related to the longevity of the fiber, which is not replaceable.

Some alternative devices were designed and built for field sampling (Figures 6 and 7). The samplers were designed with the goal to avoid the use of rubber septa as the sealing material, to eliminate or minimize contamination or losses during storage. Figure 6 presents a field sampler that does not use a septum to seal the needle. Instead, the tip of the needle is closed by squeezing a two-leaf closure. The body of the sampler is made of aluminum. Moving the barrel (3), whose position can be fixed by thumbscrew (5), can change the length to which the needle is exposed. The SPME fiber (8) can be exposed from the needle by depressing plunger (1), guided by a Z-slot. In the storage position, the tip of the needle is sealed by a nylon two-leaf closure (9) squeezed around it. The closure is sealed by tightening a finger-tight nut (10). Commercial fiber assembly (7) was used in this prototype after removing the colored hub from the inner tubing (6). Should the fiber need replacement, it can be done by introducing the inner tubing from a new fiber assembly through the needle opening and fastening it to the plunger with screw (4). Between-fiber reproducibility is strictly related to the volume of the stationary phase on the fibers. The dependence of the volume on the length of the fiber is linear, while the dependence on the thickness of the coating is quadratic. Therefore, it is very important that the stationary phase thickness and length are reproducible. This feature is guaranteed by the manufacturer.

To sample, the opening between the two halves of the closure (9) is enlarged by unscrewing the nut (10), and the needle is pushed out. To protect the fiber during sampling, a removable nylon shield (11), with large holes
SOLID-PHASE MICROEXTRACTION IN ANALYSIS OF POLLUTANTS IN THE FIELD

Figure 7 Disposable SPME field sampler with Teflon cap. 1: plunger; 2: nylon body; 3: set screw; 4: SPME fiber assembly; 5: nylon shield; 6: SPME fiber; 7: Teflon cap.

through which air or water can circulate, can be optionally mounted on the nut (10). With this device, no cap has to be removed from the body of the sampler to expose the fiber, so the sampling procedure is more rapid and simple. More advanced versions of the prototype were subsequently prepared, with two new leaf closures made of different materials (Delrin and KEL-F) with a cleaner cut between the two halves. The choice of the material is very important because it cannot be too hard so that a good seal between the two surfaces is achieved (which excludes any metal), but also cannot be too soft (e.g. Teflon) to prevent premature wear caused by the needle movement. Any kind of coating commercially available can be used with this device. The device was tested for storage with CX/PDMS 75 µm, PDMS 100 µm and PDMS/DVB 65 µm fibers.

Figure 7 shows a prototype of a rugged and disposable field sampler made of nylon. The needle tip is sealed during transport with a Teflon cap (7). The opening in the cap fits tightly the outer diameter of the needle. A nylon shield (5) can be mounted to protect the SPME fiber (6) during sampling. The plunger (1), guided by a small screw (3) that moves in a Z-slot, regulates the exposure of the SPME fiber during sampling. Any commercial SPME fiber assembly can be mounted on this device. Since Teflon is inert, it is preferred over silicone rubber as the sealing material for the SPME needle during storage. No interactions between the analytes desorbed from the fiber and the cap should occur during typical storage times. On the other hand, Teflon is soft, therefore the tightness of the cap fit can decreases with use. Besides, the cap can get lost when it is removed from the needle. The device was tested with PDMS 100 µm, PDMS/DVB 65 µm and CX/PDMS 65 µm coatings.

A different concept was also explored for field analysis purposes. An innovative field sampler (Figure 8) was designed and built by modification of a commercially available gas-tight syringe with a special valve for gas sampling (SampleLock 50 µL, Hamilton, model 80956). The syringe has a metal valve (3) that, when it is in the

Figure 8 Gas-tight valve syringe modified for SPME field applications. (a) Sampling. (b) Storage with the valve in the closed position. 1: SPME fiber; 2: inner tubing of the commercial fiber assembly; 3: metal gas-tight valve; 4: Teflon tip of the plunger; 5: plunger.
closed position, seals the air sample inside the barrel even under pressure, as specified by the manufacturer. Some modifications of the valve syringe were performed in order to adapt it for use with SPME fibers. A small hole, of a diameter closely matching that of the inner tubing (2) of the commercial fiber assembly, was drilled through the Teflon tip (4) of plunger (5). The stainless steel inner tubing of the fiber assembly was cut at a right angle so that it was completely contained inside the barrel when the plunger indicated 50 µL. The tubing was mounted by pressing it into the hole in the plunger tip. Since no glue was used, the fiber could be easily changed or replaced. When the SPME fiber (1) was exposed to the sample for extraction (Figure 8a), the valve was open, the hole inside the valve was aligned with the needle opening, and the inner tubing with the fiber could easily go through. To store the analytes during transport to the laboratory (Figure 8b), the plunger was withdrawn up to the 50 µL mark, so that a fixed amount of air was collected inside the barrel, and the SPME fiber (1) was maintained in the sample environment during storage. Should losses of analytes from the fiber occur via equilibration between the fiber and the air inside the syringe barrel, all the analytes should be injected anyway, since also the air inside the barrel is introduced into the GC column by pulling the plunger. To minimize losses due to desorption of volatiles from the fiber the volume of air in the syringe should be as small as possible. The danger of adsorption of less volatile compounds onto the glass walls of the barrel potentially exists during prolonged storage, but the interaction for the most volatile compounds should be negligible and deactivation (by silanization) of the glass surface of the barrel should prevent any undesirable adsorption.

4.1 Storage Investigations

A very important feature for an SPME field sampler is the sealing capacity during storage and transport of the sampler to the laboratory. Storage capacity of the new field samplers, described in section 4, was investigated by storing several VOCs at different temperatures on selected coatings, as described by L. Müller et al. Gaseous standards of methylene chloride, chloroform, 1,1,1-trichloroethane, benzene, toluene, tetrachloroethylene, 1,1,2,2-tetrachloroethane and 1,3-dichlorobenzene covered a wide range of volatility of the investigated compounds. Air standards (30 µg L⁻¹), prepared freshly for each experiment in 1 L glass bulbs, were extracted by exposing the SPME fiber for 3 minutes under static conditions. The following fibers were tested for storage capacity: PDMS 100 µm, PDMS/DVB 65 µm and CX/PDMS 75 µm. The 100 µm PDMS fiber is particularly suitable for investigations on the sealing capacity of field samplers, because it has the lowest affinity towards very volatile analytes. (Standards of 60 µg L⁻¹ were used for experiments with PDMS 100 µm, due to a lower response of this fiber toward the analytes investigated.) The PDMS/DVB mixed coating is a new generation fiber characterized by high affinity towards volatile and certain polar compounds. Analytes are extracted by this coating via adsorption, therefore they do not have to diffuse into the bulk of the coating material, as is the case with 100 µm PDMS fibers that extract analytes by absorption.

CX/PDMS 75 µm is a relatively new fiber created specifically for volatiles. The molecular sieve Carboxen fraction of the coating acts as a trap for volatiles, which can be desorbed only at high temperatures. From the physicochemical characteristics, the best storage efficiency should be expected for this fiber, which in theory is the best for field investigations. However, its applications are limited to very volatile compounds only.

At the scheduled time (±3 s), after storage, the fibers were desorbed in the GC injector and the analysis by GC coupled to FID (Varian 3400) was carried out. An SPB-5 column (30 m × 0.25 mm × 1 µm film thickness) from Supelco was used for separation of the analytes with the following GC parameters: oven temperature program 40 °C for 2 min, 15 °C min⁻¹ to 150 °C hold for 1 min; injector temperature 250 °C; carrier gas pressure (H₂) 30 psi. Increasingly longer storage times were investigated, from 5 min to 24 h. The dependence of storage efficiency on temperature was evaluated by keeping the samplers at different temperatures: room temperature (24 °C), fridge temperature (4–8 °C) and dry ice temperature (−70 °C). Results presented in Table 1 show the percentage of the analytes retained by the SPME fiber after 24 hours storage, evaluated by comparison with the amount extracted and immediately desorbed in the GC injector. Two values are given, one for the most volatile, and one for the least volatile analyte. If not otherwise specified, the first number corresponds to chloroform and the second number to 1,1,2,2-tetrachloroethane. As expected, cold storage significantly reduces losses of volatile analytes from the fiber. However, certain drawbacks occur due to the low temperature of the device when storing the field sampler in dry ice (−70 °C). They include mechanical problems with the movement of the inner tubing through the septum of the fiber assembly, as the septum becomes very hard at low temperatures. For this reason, after storing any sampler in dry ice, a few minute warm-up at room temperature was required before injection, especially with metal devices. It can be noticed that refrigerated storage (4–8 °C) can generate some unexpected results, e.g. storage percentages of more volatile compounds higher that those of less volatile analytes. This behavior can be explained assuming that significant contamination could have occurred in the refrigerator, where high
concentrations of solvent vapors were present. This means that good sealing during storage is important not only to avoid losses of analytes from the fiber, but also to prevent contamination from the outer environment where the sampler is kept during transport. This effect is especially noticeable for the CX/PDMS fiber, with the highest affinity towards the most volatile compounds.

As expected, the most volatile analytes are retained to a lesser extent by the SPME fiber during storage. The 100 μm PDMS fiber, which showed the worst storage capacity of all the devices investigated, could not retain any chloroform for 24 h of refrigerated storage with any of the samplers investigated, with the exception of the Teflon capped sampler, which still retained 38% of the compound on the fiber. The performance of the valve syringe was undoubtedly the best, especially considering that a PDMS fiber was used for the investigations: storage of 86% of methylene chloride after 24 h in the refrigerator was an excellent result. Even at room temperature, the device showed much better performance compared to the other designs. Only a 100 μm PDMS fiber was used for storage investigations with the valve syringe device, since it was assumed that if the device works well with the coating that performs the worst, it should work even better with the remaining coatings. Low storage capacity of the Supelco field sampler, evident for long storage times, confirmed that silicone rubber septa are not well suited to prevent the release of volatile compounds from the fiber.

According to expectations, the 75 μm CX/PDMS was the coating that showed the best storage capacity itself, no matter how the needle was sealed. For instance, even after 24 h of storage on dry ice, over 70% of chloroform was still on the fibers with all the devices investigated. Other storage investigations with this coating reported in literature showed that a 3-day storage, even of very volatile compounds, can be achieved without considerable losses from the fiber.\(^{22}\)

The 65 μm PDMS/DVB fiber was not tested with the Supelco field sampler, because the device was not commercially available with this coating. In general, decreasing the temperature of storage, as shown by experimental data, consistently enhanced storage capacity for PDMS/DVB. Even though contamination occurred during storage due to the presence of organic solvents in the refrigerator, good storage efficiency could be achieved with this coating with the Teflon capped device (Figure 7) when the sampler was kept on dry ice for 24 h (Table 1).\(^{23}\)

### 4.2 Field Applications

The authors performed some field evaluations of the recently developed prototypes of the field samplers.\(^{23}\) Since the valve syringe (Figure 8) was the experimental device that showed the best storage efficiency during laboratory experiments, it was compared to the field sampler commercialized by Supelco in a field investigation of air samples. Analysis of indoor air in an organic laboratory of the Chemistry Department of the University of Waterloo (ON, Canada) was performed with 100 μm PDMS fibers (for this experiment the CX/PDMS fiber in the commercial field sampler was replaced with the PDMS fiber). For field sampling, the air inside the cabinet where organic wastes were stored was extracted by exposing the SPME fibers of the two devices under static conditions for 3 min. The fibers were immediately desorbed and analyzed by GC coupled to FID to obtain reference chromatograms. Extractions were then repeated, and the devices were stored for 150 min at 4 °C. Storage capacity was evaluated as percentage, by comparing the area counts of the

peaks in the chromatograms before and after storage. This experiment confirmed the superiority of the valve syringe for the storage of volatiles. Compounds from the volatility range between chloroform and toluene were found on the fiber after 150 min at 4°C in percentages between 53.6% and 60.5% for the valve syringe device, and between 21.1% and 49.8% for the Supelco field sampler. Taking into account that the experiment was carried out with PDMS fibers, the result obtained for the valve syringe was very good.

Another field sampling session with the 50μL valve syringe was performed with a 75μm CX/PDMS fiber, which is more suitable for field investigations of volatiles. Scents released by a lilac bush were extracted by wrapping a lilac flower directly on the plant with a plastic bag, and exposing the fiber to the headspace of the flower for 3 min. One sampler was then stored for 20 h at room temperature before desorption in a GC/FID instrument, while the other was immediately carried to the laboratory and analyzed (3 min were required to reach the laboratory). A comparison of the chromatograms obtained with and without storage is presented in Figure 9. Even after 20 h losses of analytes were minimal, as the relative area counts were close to 100%.

The success of this sampling experiment for volatile compounds was determined both by the performance of the sampler, and by the suitability of the CX/PDMS coating to this kind of analysis. The collection of a small portion of air inside the gas-tight syringe improves the sensitivity of the method, and guarantees the injection of almost all the analytes extracted by the fiber during field sampling. Besides, the valve syringe proved to be practical and easy to use for field investigations where retraction of the fiber after sampling had to be fast and easy. The syringe needle was removed during storage, so that contamination due to adsorption of chemicals on the steel walls of the needle was minimized and the device was easier to store and transport.

5 CONCLUSIONS

Several field applications of SPME were recently described in the literature. They utilized either a portable instrument for fast GC, or dedicated devices for SPME field sampling. An increasing number of field applications is expected in the future due to the particular suitability of this technique for field investigations, for a variety of reasons described herein that make SPME an excellent tool for field investigation. Recent development of portable fast GC instrumentation that allows fiber desorption directly in the field further decreased the time of the entire analytical procedure, already reduced by using SPME as sampling and sample preparation technique in one single step rather than in many, as is the case with traditional techniques.

The opportunity of sampling in the field and transporting the device to the laboratory for instrumental investigation seems attractive, if appropriate devices are used. The commercially available device is well suited for sample storage provided a coating most appropriate
for the analytes examined is used. It performs well for volatile compounds when equipped with the Carboxen™ coating. The pen-like device with a leaf closure is a very elegant concept. To perform according to expectations, more sophisticated methods would have to be used for the manufacture of the leaf closure, to assure a complete tightness once the leaves are squeezed by the nut. Once this is achieved, this device would probably be the most convenient for field sampling. On the other hand, the nylon holder with the Teflon cap could easily be manufactured as a low-cost, disposable device. The sealing method used in this holder proved to be superior to sealing with a silicone septum, and the entire device could be manufactured by injection molding. The cap itself could be made of a cheaper material, e.g. high-density polypropylene. It could be strapped to the device to prevent losing it in the field.

Excellent storage, even of very volatile compounds, was achieved using a modified gas-tight syringe equipped with a valve that sealed the environment inside the syringe barrel where the SPME fiber was placed during storage. The device would be ideally suitable for sampling and storage of volatile analytes. Concurrent injection of a small amount of air can potentially increase the sensitivity for the most volatile analytes. The drawback of this device is the relatively high price of the syringe itself. For less demanding applications, the cheaper devices described above would probably be more suitable.

Very promising applications, from indoor air monitoring to groundwater and flower scent analysis, open the frontiers of field sampling by SPME.

REFERENCES

Remote and in-field analysis is developing into a crucial aspect of modern analytical chemistry. Chemical sensors, which are small measuring devices consisting of a recognition layer, a transducer and the measurement electronics, have proven to be highly suitable tools for this purpose. Although usually they are constructed for the detection of very limited amounts of chemical compounds and often do not reach the detection limits of modern analytical instruments, they show very desirable advantages: the systems are easy to operate, mostly rugged, small, good value and can be manufactured by established technological methods. Due to their size and ruggedness they can even be operated in harsh environments and often they can be constructed to be suitable for remote measurements, where several sensors are interrogated by a central analytical site.

Devices being used include optical fibers, field effect transistors (FETs), electrochemical cells (be they potentiometric or amperometric) and mass-sensitive components of all kinds. The chemically-sensitive coatings range from bare transducer surfaces to dyes reacting with analyte or sterically-specific binding sites (host–guest complexes etc.). A seeming drawback is the fact that only few sensors react specifically towards one defined component but normally show a sensitivity pattern towards chemically-related substances. By using an array of several components followed by modern methods of data evaluation (such as neural networks) a group of analytes can be detected and characterized simultaneously. This article introduces device and recognition layer principles as well as covering field sensors published during the last one and a half decades based on all the different kinds of transducers and sensor layers. Some of the devices (such as the lambda probe) are already marketed, others are developed to a stage where field measurements have already been carried out, but which are not market-ready.

1 INTRODUCTION

Public sensitivity towards environmental pollution has greatly increased during the last few years. This has resulted in a growing demand for analytical tools suitable for the fast and economic determination of contaminants in soil, water and air. Additionally, remote and in-field measurements are becoming more and more important.(1) Different strategies can be used for fulfilling these needs: the first possibility is to miniaturize classical analytical instrumental techniques such as gas chromatography (GC),(2) mass spectrometry (MS) and electrophoretic systems and also detectors such as flame analyzers,(3) and the second is the use of chemical sensors. The latter have established themselves as an important field of analytical chemistry and are defined as follows:(4) “Chemical sensors are (small) devices capable of continuously recognizing concentrations of chemical constituents in liquids or gases and converting this information in real time to an electrical or optical signal”. Hence the aim of a sensor is to translate chemical information into a measurable quantity, usually an electronic one. Figure 1 shows the scheme of a chemical sensing system.(5) It consists of a sensitive layer, a transducer and a data processing unit. The sensitive layer is exposed to the analyte and is able to interact with it. Upon this interaction, one of the layer’s physical properties changes (e.g. polarity, optical absorbance, fluorescence behavior, mass).(6) These changes are detected by the transducer, which converts them to an electrical signal. Finally, the data obtained are processed and stored.

Usually a chemical sensor does not react specifically towards a defined compound but shows a certain sensitivity pattern towards a class of chemical substances. This can be overcome in two different ways: either the samples are preseparated (which actually contradicts the

2 DEVICE PRINCIPLES

A wide variety of devices are suitable as transducers in chemical sensing, which can be classified according to the signal generation principles. One can distinguish between different kinds of electrochemical (potentiometric, amperometric, etc.), optical and mass-sensitive devices as well as pellistors, which will be discussed in the following sections.

2.1 Electronic Devices

Some of the commercially most successful sensor devices such as the Figaro sensor, the lambda probe and the chemically sensitive field effect transistor (ChemFET) operate with components measuring an electrochemical or electronic quantity, e.g. changes in surface charge, in chemical potential or in current.

2.1.1 Potentiometric Sensors

Several of very popular chemical sensors are based on potentiometric devices, whose measurand is the potential difference between a measuring electrode and a reference caused by different analyte concentrations. An early integrated device for this purpose is the glass electrode for pH measurements (Figure 2), which today is standard laboratory equipment and actually would not now be called a sensor owing to its size. Continuous development led to a highly integrated device, the FET, which will be discussed separately. Other examples of potentiometric sensors are all kinds of ion-selective electrodes with either solid (e.g. LaF$_3$) or liquid membranes. The most widely used potentiometric sensor based on ionic conductivity in a solid is the lambda probe. It consists of ZrO$_2$/Y$_2$O$_3$ where charge is transported via oxygen ions. The electrolyte separates the sample and reference chambers and the signal is obtained in this concentration cell according to Nernst’s law.

2.1.2 Conductometric Devices

A widely applied conductometric sensor is the so-called Taguchi or Figaro sensor, which was first used commercially in 1968 for the monitoring of ambient combustible gases in households. It consists of SnO$_2$,
usually doped with a noble metal such as Pt or Pd. In the crystal lattice oxygen defects are generated, resulting in an n-type semiconductor. When exposed to the atmosphere the ceramic material adsorbs oxygen, which is reduced by conducting electrons of the semiconductor, resulting in a change in surface resistivity. Ambient combustible gases react with the oxygen present on the device, thus reversibly decreasing its surface concentration, which leads to an increase in conductance due to an increase of electrons in the matrix. These kinds of sensors also are highly field-capable: although they have to be heated (usually they operate at temperatures of about 350–500°C), they can easily be miniaturized, thus dramatically lowering their power consumption. This also allows the feasible combination of several devices to give an array without the need for too much space, which offers the possibility of simultaneous multicomponent sensing.

2.1.3 Amperometric Devices

Amperometric devices use the current accompanying an electrochemical reaction as a measurand. One of the best known examples of this kind of sensor is the so-called Clark electrode for the detection of gaseous oxygen. It consists of a platinum and a silver electrode (working as anode) and KOH as electrolyte. Oxygen is reduced and silver is oxidized. Although it is a powerful sensor, the Clark cell also shows the inherent disadvantage of all amperometric sensors: the silver electrode is dissolved during the measurement (and precipitates as silver chloride), thus allowing only a restricted operational time. To economize on silver, an auxiliary Pb electrode can additionally be used, although this does not alter the fact that the electrode material is consumed during measurements. Nonetheless, this type of sensor can be used for discardable one-way systems owing to the usually low costs. Other examples of amperometric cells include biochemical systems, e.g. for glucose.

2.1.4 Field Effect Devices

One can distinguish between two principal types of electronic devices, namely active and passive devices. Active devices directly yield a comparably huge current by using comparably low control voltages, i.e. they usually act as amplifiers yielding a more powerful output than the input signal. Field effect devices exist as both active and passive components. Capacity diodes based on a metal–insulator–semiconductor design are passive whereas FETs are active devices. Two acronyms are often used with respect to field effect devices, namely MOS capacitor and diode, where MOS means metal oxide semiconductor and MIS meaning metal insulator semiconductor. The two abbreviations denote the sandwich structure of which the device is made and are synonymous.

MIS capacitors and diodes consist of a semiconducting material (usually Si) on which a thin insulating layer is generated by oxidation (often SiO₂). Finally, a metal coating, usually Pd or Pt, is applied. When using a capacitor, the voltage dependence of the capacity under changing ambient conditions is observed; in the case of a diode the current–voltage characteristic is measured. The signal is obtained by adsorption and dissociation of analytes on the metal surface. Additionally, there is an equilibrium between atoms adsorbed there and those adsorbed on the boundary between metal and insulator where they become polarized leading to a shift in voltage (Figure 3).

Bergveld introduced the first ion-sensitive field effect transistor (ISFET) in 1970, which can be regarded as the beginning of chemical sensors based on FETs. The principle of a FET is shown in Figure 4. It
normally consists of a p-type semiconductor with two n-doped regions near to each other, the source and the drain which are contacted by the respective electrodes. The third electrode (the gate) is mounted above the region between the source and drain. By variation of the potential at the gate electrode, the current between the other two electrodes is influenced, the chemically sensitive layer is applied to the gate electrode. The great advantage of FETs is their fast reaction towards changes in ionic or dipolar properties and the fact that they provide directly an electronic signal that is easy to measure. Additionally, they react very fast to changes in their chemical environment. Nonetheless, they have an inherent limitation: the signal generated shows long-term drift if the isolation materials are not perfectly manufactured. Existing temperature drift can be compensated for by combining at least two devices on one semiconductor substrate, where one FET is tightly encapsulated and used as a reference field effect transistor (REFET). Existing external limitations can be overcome by proper encapsulation and electronic isolation and also by using a REFET. In an array one can additionally measure the difference signal between the sensor and reference, thus improving the signal-to-noise ratio.

FETs can also be used for gas sensing, e.g. for the detection of hydrogen. In this case the gate is coated with a noble metal (e.g. Pt or Pd), where the sensing mechanisms are the same as for MIS devices. Variation of the metal coating results in enhanced selectivity towards different analytes. A novel approach is the use of a suspended-gate field effect transistor (SGFET), where a thin air gap (about 100 nm) is placed below the gate electrode, where the adsorption takes place.

Another field of application for FETs is biosensing: here usually a bioactive layer is deposited on an ISFET (e.g. enzymes such as peroxidase). Usually the actual measurand is a change in hydrogen ion concentration via a pH-sensitive layer. A wide variety of biosensors can be found in the literature.\(^{22}\)

2.2 Pellistors

Pellistors are used for the measurement of reducing gases and consist of a ceramic material (mostly ThO\(_2\) or Al\(_2\)O\(_3\)) doped with a catalyst (Pt or Pd) and a thermoresistive element\(^{(23)}\) (see Figure 5). The entire device is heated. Ambient reducing gases are adsorbed on the surface and react catalytically with oxygen. The resulting combustion heat changes the sensor temperature, resulting in a variation of resistivity. Pellistors are easy to produce and cheap and very reliable but have the major drawback of not being selective.

2.3 Optical Devices

In contrast to the devices introduced up to now, the chemical information in the case of an optical sensor is not directly transformed into an electronic quantity but is obtained as a change in an optical property, such as absorption or fluorescence. Wolfbeis edited a comprehensive introduction to the field of fiber-optic chemical sensing.\(^{(24)}\) Optical methods making use of all parts of the electromagnetic spectrum are well established in analytical chemistry and for structure determination. The breakthrough in the use of these methods for chemical sensing applications came with the development of waveguide fibers. These were originally designed for telecommunications technology and made it possible to transport light over long distances using a very small cross-sectional area. For sensing applications this offers the major advantage of bringing the device to the potential analyte instead of the other way round. The distances covered by fibers commercially available in large quantities at a suitable price can reach up to 1000 m. The next major improvement in optical chemical sensing was the development of the inexpensive light-emitting diode (LED) for wavelengths reaching from the ultraviolet (UV) to the near-infrared (NIR) region. Two different types of optical sensors can be distinguished: plain fiber sensors, making use of the direct influence of the analyte on the optical information, and indicator-mediated sensors, where the analyte interacts with a dye (forms an equilibrium), which results in a change of the dye’s optical behavior.\(^{(25,26)}\)

Fiber-optical systems additionally offer the possibility that a bundle of fibers reaching different spots of
analytical interest can be combined and interrogated by a single controlling device, thus leading to a comparably easy possibility of supervising a larger area via a central basis station. This also makes complicated sampling procedures redundant, which especially in the case of environmental monitoring can be very time-consuming.

Optical sensors have a wide variety of advantages:

- light can be transmitted over long distances, thus bringing the measuring device to the analyte;
- if several fibers optimized for different analytes are combined in a bundle, simultaneous monitoring of several different compounds is possible;
- optical methods usually do not consume analyte and leave it chemically unaffected;
- fiber optics are produced from materials that usually are highly stable and thus can also be operated in harsh environments;
- the light can be guided to different locations, thus offering the possibility of comparably easy measurement of spatial distributions of an analyte.

Some of the drawbacks are as follows:

- indicators tend to undergo photobleaching or bleeding, which is especially adverse for measurements in the liquid phase;
- ambient light can cause undesirable interferences.

Although almost all methods of optical spectroscopy are suitable for chemical sensing applications, mostly fluorescence and absorption spectroscopy are used, preferably in the visible and near-UV range of the spectrum, even though devices operating in the NIR and middle-infrared (MIR) regions are becoming increasingly important.

A special class of chemical sensors is based on surface plasmon resonance (SPR). Such a system consists of a prism brought to optical contact with a thin noble metal layer. When measuring the reflectance of this metal as a function of the angle of the incident beam of light, a sharp minimum occurs. At that distinct angle SPR is induced, which leads to a change in light reflectivity. By application of a suitable chemically sensitive layer to the metal surface, the effect can be used for chemical sensing; especially biosensors based on this effect have been reported. Thus SPR phenomena, which are oscillations in the metal electron gas, are strongly dependent on the properties in the direct vicinity of the metal and therefore react towards chemical changes in their environment.

### 2.4 Mass-sensitive Devices

Monocrystalline piezoelectric materials such as quartz (actually the most important material in this field) and lithium tantalate can be used very advantageously in chemical sensing. On applying an alternating current to a crystal plate of such a material cut at a specific angle, a mechanical oscillation is induced, and both surface and bulk waves are observed (depending on the cutting angle). It was shown by Sauerbrey in 1959\(^ {28}\) that the resonance frequency of such an oscillator is highly dependent on the mass present on the electrodes. Hence these devices act like small and highly sensitive balances. In combination with chemically sensitive layers suitable for the selective inclusion of a certain analyte, they form powerful sensors.

The most widely used mass-sensitive devices are quartz microbalances (QMBs) and the surface acoustic wave (SAW) resonator. A QMB (see Figure 6) consists of an AT-cut quartz plate on which an electrode is applied on each side. When an alternating current is applied, a thickness shear wave is generated in the substrate, the resonance frequency of which is mainly determined by the thickness of the quartz plate. Commercial QMBs are available for frequencies up to 20 MHz; above that limit the plates would become too thin to be mechanically stable. In sensor applications usually resonance frequencies around 10 MHz are used. Despite their relatively low fundamental frequency, QMBs are a powerful tool in sensing applications, especially when ruggedness and comparably low sensitivity towards
ambient parameters (e.g. high damping by liquids) is needed.

SAWs, on the other hand, are produced from ST-cut quartz plates where an interdigital transducer (IDT: comb electrode; see also Figure 7) is generated by a lift-off process. Application of an alternating current creates a surface wave in the quartz, which is detected by a second IDT on the substrate. SAWs can be operated in frequency ranges up to 2.5 GHz and analytical applications have been reported up to 1 GHz\(^{(29)}\) which means greatly increased sensitivity towards mass loading compared with QMBs. The drawback is that normal SAWs cannot be used in the liquid phase owing to excessive damping of the surface wave. A possibility of overcoming this problem is the use of the so-called shear wave resonator.\(^{(30)}\)

### 3 SENSITIVE LAYERS

Many of the devices introduced above cannot distinguish between different chemical species (e.g. mass-sensitive devices, some optical devices) and thus need a layer whose interaction with the analyte is then transformed into the electronic or optical signal, respectively. In general there are two different types of sensitive layers: the first interacts with the analyte forming an adduct or something similar due to chemical interactions or reactions, whereas the second offers spatially fitting cavities for analyte inclusion which can additionally offer binding sites for polar interactions such as hydrogen bonds (figuratively there are convex interaction sites, where the analyte is somehow captured by a surface, be it external or internal, and concave sites, where the analyte is encompassed in a cavity of the matrix). The interactions used for sensing applications include dipolar interactions, hydrogen bonds, \(\pi-\pi\) interactions, donor–acceptor interactions and discrimination via steric properties.

Affinity layers usually consist of a medium holding the respective receptor. The best known examples of such materials are all kinds of pH indicators, which are widely applied in sensing, but also other dyes showing, e.g. solvatochromism. Other examples of affinity layers are polymers containing polar groups or side chains, e.g. for humidity monitoring.

Two principal approaches are used for the synthesis of cavities tailored for the spatial requirements of a certain analyte: supramolecular chemistry and molecular imprinting. In supramolecular chemistry, molecules containing a cavity with a size suitable for the incorporation of a special analyte are synthesized. Examples of molecules offering cavities of suitable size are differently substituted cyclodextrins, paracyclophanes, calixarenes and calix-resorcinarenes, all of which have already been reported in sensing applications.\(^{(31)}\) The synthesis of this class of compounds is often assisted by computer modeling to obtain hints for faster manufacturing. Nonetheless, their synthesis is rather sophisticated and time-consuming. For increased chemical and mechanical stability, these cavities can be embedded in a supporting polymer.

The other innovative approach to the synthesis of potential sensor materials is the method of molecular imprinting\(^{(32,33)}\) (see Figure 8). Here cavities are generated in a highly cross-linked polymer by mixing its precursor compounds with the analyte, forming a kind of synthetic antibody. Polymerization takes place in the presence of the template, which does not participate in the formation process. When synthesis is completed, the template is removed from the material, leaving behind adapted cavities and diffusion pathways. The great advantages of this method are both the compatibility with technological processes, which makes it very promising for mass fabrication, and the speed with which the respective layers are obtained. Large amounts of cross-linker are used for synthesis to stiffen the polymeric material, thus preventing the system from collapsing after removal of the template molecule. This also results in mechanically and chemically stable materials which show advantageous features for use in harsh environments.

For molecularly imprinted polymers, it is usually difficult to do preliminary computer calculations, but fortunately this is not required as the steric properties of the template exert a direct influence on the shape of the hollows. In the initial stage of research, the template was linked to one of the monomer compounds either by covalent bonds or by polar interactions, which adds chemical recognition to the sterically fitting cavities. Nonetheless, there are also possibilities of generating suitable hollows determined only by van der Waals interactions, thus offering purely steric recognition sites. For the synthesis

![Molecular imprinting](image-url)
of molecularly imprinted sensor materials one does not need to know the exact chemical composition of later analytes. This leads to the possibility of designing sensors even for substances which are not exactly known, or for complex mixtures, thus pushing forward the frontiers of chemical sensing.

4 SELECTED SENSING APPLICATIONS

Many papers on sensors are published every year and many of them are related to environmental sensing applications. In this article we want to concentrate more on sensing systems for environmental and ambient parameters than on sensors specifically designed for industrial or technological process control. In the following sections the sensors will be arranged according to their transducing principle rather than according to the analytes of interest. Nonetheless, some general articles and reviews will be included, such as those dealing with environmental sensing. A review on air pollution and its detection methods was published by Fox in 1987, and environmental gas sensing has been reported. Fox’s paper covers mainly different publications on pollution monitoring by a variety of analytical methods and also includes an extensive list of references. An electrochemical sensor array for the simultaneous determination of water quality parameters (pH, conductivity, temperature, redox potential and dissolved oxygen concentration) has been reported and evaluated by a group from Southampton. In this case the sensor approach is illustrated by combining several measuring devices suitable for very different analytes or physical quantities. In combination with an appropriate method for data evaluation, a broad range of ambient parameters can be simultaneously monitored and evaluated in real time.

A special task of in-field sensing is the monitoring of traces of explosives, which is needed, for example, for the detection and removal of land mines. A short overview of the development of sensors for military uses (also on the battlefield) has been given and a review of the detection of clandestine explosives has been published.

4.1 Electrochemical Sensors

Miniaturization is a key step in the development of chemical sensors, but this was difficult to achieve for electrochemical applications owing to a lack of suitable reference electrodes. A paper by Suzuki et al. deals with the production of an integrated three-electrode system for electrochemical sensing to overcome this problem. They reported the design of a liquid-junction Ag/AgCl electrode suitable for miniaturization and showed the design of an integrated chip including working, counter and reference electrodes in thin-film technology. This system’s ability as a tool for electrochemical analysis is demonstrated by the example of a glucose sensor. The device is a great leap towards a good-value dischargeable tool suitable for industrial mass production.

4.1.1 Conductivity Sensors

As already stated, the so-called Taguchi or Figaro sensor was one of the first sensors to become commercially available. This type of sensor usually consists of a semiconducting metal oxide (e.g. SnO₂) which adsorbs oxygen from the ambient atmosphere. Theory indicates that electrons are transferred from negatively charged sites on the surface to these adsorbed atoms, thus leading to a decrease in surface conductivity (i.e. oxygen is reduced by conducting electrons). Reducing gases can react with the adsorbed oxygen, thus causing an increase in surface charge leading to a higher conductivity. As all the reactions occurring are reversible, devices operating with this principle meet the requirements of a chemosensor. An introduction to tin dioxide sensing was given by Takahata, where not only are laboratory processes for the production of thin- and thick-film sensors described but also outlines for the solving of a basic problem in using this type of sensor are given. The fundamental drawback mentioned is the increase in the material's surface charge density with time and the problems caused by false alarms as a consequence. The effect has both reversible and irreversible causes, which can be attributed to elevated temperatures (above 500 °C) according to the analyte’s heat of combustion and ambient humidity. Obviously tin dioxide from inner parts of the sensor is deposited on the outside, leading to a decrease in catalyst surface concentration. A way to overcome this difficulty is to dope the sensor material with vanadium. In addition to the introduction of the drift effects mentioned, the article also gives a short overview of other types of analytes and the resulting applications based on tin dioxide sensors.

The problems of increasing sensitivity with time (so-called 'hypersensitivity' leading to false alarms) and the working conditions of SnO₂ sensors in the field were comprehensively discussed by Nakamura. Decreasing device resistance is mainly traced back to effects caused by multiple exposure to combustible gases resulting in longer periods at temperatures higher than 550 °C. As a result, Nakamura observed three effects, namely a decrease in water desorption, substantial changes in the tin dioxide crystal structure and a decrease in Pd dispersion. All these parameters lead to a denser packing of the ceramic material and variations of the surface structure, thus aggravating analyte diffusion to the reactive parts in the matrix.

Hübner and Obermeier reported basic studies on semiconducting materials suitable for carbon monoxide...
sensing,\(^{(51)}\) and later Barbi et al.\(^{(52)}\) reported sensors for the monitoring of CO in urban environments [for carbon dioxide, see Kaneyasu et al.\(^{(53)}\)]. Carbon monoxide is a highly toxic pollutant occurring mainly as a consequence of incomplete combustion processes. The authors reported grain-size sensors suitable for the detection of CO at concentrations down to a few parts per million. Additionally, cross-sensitivity towards NO\(_2\) is discussed, which contrary to CO is an electron acceptor and thus shows reverse effects on surface charge. Figure 9 shows the solution to this problem by choosing an appropriate temperature. Another sensor system for the monitoring of ambient traces of CO and NO to regulate the atmosphere inside a car for the prevention of passenger casualties has been proposed by Wiegleb and Heitbaum\(^{(54)}\) based both on indium and tin oxides. Their sensor set-up includes both ceramics on one component. Figure 10(a) and (b) presents the results obtained for the two devices. Torvela et al. studied the influence of humidity on thick-film tin dioxide gas sensors for the use of emission control in power stations.\(^{(55)}\)

Gaseous CO\(_2\) can also be determined by metal oxide semiconducting devices. Hanada et al. described a system consisting of an La-doped tin dioxide sensor combined with a reference and a filter for the removal of alcohol.\(^{(56)}\) Comparison of data obtained by field measurements with infrared (IR) methods showed the high potential of the device.

A sensor array consisting of three different metal oxide sensors for the simultaneous detection of methane and ammonia in the presence of ambient humidity has been reported.\(^{(57)}\) Data evaluation is done by the means of artificial neural networks and the relative errors for the quantitative determination of the analyte are below 5\%. As the monitoring devices are located on the same substrate, interferences caused by material defects, etc. are compensated for. Here again it can be seen that by methods of modern data analysis applied to sensors with different sensitivity patterns all analyte concentrations of interest can be determined without a sensor reacting specifically and exclusively to one analyte.

A possibility for designing tin dioxide thin films with enhanced sensitivity based on layers fabricated by the sol–gel process, which is a very innovative method for the synthesis of ceramic material, has been introduced together with mechanistical studies of the material.\(^{(58)}\)

Perovskite-type thick-film sensors reacting towards environmentally hazardous gases have been proposed and field tested by Martinelli et al.\(^{(59)}\) They used printed thick films of SmFeO\(_3\) and LaFeO\(_3\) as sensitive layers, both being p-type semiconductors. All materials used are characterized according to structural and sensing properties. The perovskite-type materials were combined with tin dioxide devices to form an array which was tested in an Italian pollution measurement station where the signals could be compared with those obtained by classical analysis. Figure 11 shows the signals for NO obtained both by the LaFeO\(_3\) sensor and the reference station during a 2 day measurement period. The excellent correlation between the two data sets can
clearly be seen. Nitrogen dioxide is also an environmental pollutant requiring thorough monitoring. Nelli et al.\(^\text{60}\) reported a sub-parts per million NO\(_2\) sensor based on titanium–tungsten oxides suitable for the detection of traces down to concentrations below 1 ppm (see Figure 12), and discussed the effects of ambient humidity.

Ozone has become a substance of interest for environmental analysis owing to its high toxicity and the fact that its concentration in atmospheric layers near ground level has been increased mainly due to NO\(_x\) emissions. Takada et al. introduced a sensor system for O\(_3\) based on thin-film In\(_2\)O\(_3\) semiconductors.\(^\text{61}\) Thin-film technology has to be used owing to the low stability of ozone: in a thick-film sensor it would decompose before reaching the core of the sensing material. The influence of reducing gases on the sensor signal can be eliminated by coating the entire system with a thin layer of SiO\(_2\). Figure 13 shows a sensor set-up without this ‘protective’ layer, and in Figure 14 the sensitivity of sensors with several film thicknesses is plotted versus temperature. The results clearly indicate an ideal operating range for the device and that increasing height of the sensitive layers strongly decreases the sensor response. The sensors obtained underwent a long-term test and field testing with the results shown in Figure 15. WO\(_3\) has also proven to be a suitable material for ozone sensing, permitting analysis down to the parts per billion level.\(^\text{62}\) Figure 16 shows a comparison between the solid-state sensor used and a classical UV analyzer during a field measurement. The very good agreement between the two methods can easily be seen and proves the sensor’s suitability for this analytical task.

Another analyte of environmental interest is ammonia in air. Although NH\(_3\) potentially reacts with sulfur and nitrogen oxides, an excess amount in air is a potential hazard. One of the main sources of atmospheric ammonia is livestock buildings. A sensor based on Cu-doped SnO\(_2\) thick films for the monitoring at such sites has been reported.\(^\text{63}\) Figure 17 shows the response...
of this sensor towards ammonia in humid air, where
the humidities correspond to values typically found in
livestock buildings. The authors also reported field testing
of the device which has proven to be useful for a
prolonged period of time. Another promising material
under development for this purpose is molybdenum
oxide.

A further application of tin dioxide sensors, where
commercial testing devices are reported to be available,
is in odor sensing, where the sensors were optimized
for the detection of organic sulfides. A sensor system for
the monitoring of H₂S in urban environments based on
Ag-doped tin dioxide devices has been published and
tested by Lantto and Mizsei.

An approach for the detection of organic contaminants
in water has been reported by Straková et al. For the
determination, a standard SnO₂ sensor was used, the
analytes being extracted via a silicone-rubber membrane.
The authors reported the determination of several oxy-
genated, chlorinated and aromatic compounds. Whereas
all sensors introduced up to then were designed for the
monitoring of H₂S in urban environments based on
Ag-doped tin dioxide devices has been published and
tested by Lantto and Mizsei.

4.1.2 Potentiometric Sensors

Some potentiometric sensors for different analytes such as
oxygen, chlorine, SO₂ and SO₃ were introduced by Kleitz
et al. The best known potentiometric sensors are the
lambda sensor and ion-selective electrodes, as already
stated above. To complement the lambda probe, Meixner
et al. made suggestions they proposed nitrogen oxides
and carbon monoxide as additional analytes because they
doubt whether oxygen alone is a suitable analyte for
the determination of the optimal ratio between fuel and
air for combustion. They used SrTiO₃ for the lambda
probe, Al₂O₃/V₂O₅ for NOₓ and Ga₂O₃ for CO and
reported good laboratory results. The background for this
proposition is the fact that a deviation of the ideal lambda
value by as little as 0.001–0.002% decreases the catalyst
efficiency from 98% to 85%. The adjustment is especially
difficult during starting, braking and accelerating a car.

To complement the Sr titanate devices, Schreiner
and Härdtl introduced ceramics based on the formula
SrTi₁₋ₓFeₓO₃, being highly suitable for oxygen sensing
applications as the signal is comparably insensitive to
temperature. Generally this is a crucial aspect as
eengine temperature is highly dependent on the time, style
and environment in which it is operated.

A concise overview of the research on sensors for
SO₂ and SO₃ was given by Worrell and Adachi and
Imanaka. Worrell introduced K₂SO₄, Na₂SO₄ and
Li$_2$SO$_4$ as potential solid electrolyte materials. Figure 18 shows such a cell with an included reference electrode suitable for measuring different amounts of sulfur dioxide. Another class of promising sensors for this purpose is thin-film sulfate electrolyte sensors based, e.g., on Nasicon (a polymeric Na-selective material) membranes (see Figure 19). A hand-held system for the determination of different inorganic ions via interchangeable sensor tips has been reported by Ross et al.\textsuperscript{73} The device has proven its reliability in the analysis of drinking water, whereas other applications require further investigation. The ion-selective planar sensor strip can easily be changed, so a variety of analytes can be determined consecutively. The same group has additionally introduced a miniaturized flow-through system for the on-line detection of nitrate ions in water samples.\textsuperscript{74} Figure 20 shows a block diagram of the device; the authors reported an operational range between $10^{-5}$ and $10^{-2}$ mol L$^{-1}$.

Another approach for ion detection in wastewaters is the use of chalcogenide glasses as chemical sensors.\textsuperscript{75} Among the ions detected are copper, iron, mercury and cadmium, which are all interesting for the analysis of, e.g., industrial wastewaters. Figure 21 shows the response of the copper-selective sensor during a field measurement in industrial wastewater control. In another paper,\textsuperscript{76} a thallium-selective electrode was described and in Figure 22 one can see the sensor curve obtained for natural waters doped with different amounts of thallium.

Also dealing with water quality determination, Sakai et al. introduced a multichannel potentiometric sensor.
and used, and depends linearly on analyte concentration, which eases data evaluation. Parellada et al. gave an overview of amperometric field sensing devices based on biorecognition principles. An amperometric sensor for the detection of nitrogen oxides has been suggested by Tierney et al. They use a Back Cell design where the analyte does not diffuse to the electrodes through the polymeric electrolyte but from the porous ceramic back side of the device. Diffusion through these pores is substantially faster than through a polymeric matrix, making the response much more rapid than for classical devices. The measurements take place at the so-called triple points which represent the boundaries between the electrolyte, the electrode and the gas present in the pores. Discrimination between NO and NO₂ is achieved electrochemically: both are oxidized on gold electrodes at similar potentials, but nitrogen dioxide also shows reductive behavior in the range of potential used. Figure 23(a) and (b) depicts the calibration curves for both of the analytes in air, proving the potential of the sensor.

Amperometry offers a promising approach in the determination of H₂S in aquatic resources. This highly toxic substance is abundant in all systems, where sulfidic for the determination of river water quality. They used a set-up with eight different sensitive lipid layers and the results obtained in eight-dimensional space were analyzed and visualized via principal component analysis. This method usually yields parameters whose physical meaning is unknown but they are nevertheless suitable for qualitative predictions and quantitative rankings.

4.1.3 Amperometric Sensors

Amperometry uses the electric current associated with an electrochemical conversion when a defined voltage is applied. This measurand can be absolutely determined, which means that no reference system has to be defined.

Figure 21 Field-measurement data for a copper-selective potentiometric sensor.

Figure 22 Calibration curve for a thallium-selective potentiometric sensor obtained in natural water doped with thallium.

Figure 23 Sensor curves for (a) NO₂ and (b) NO for an amperometric NOₓ-sensor developed by Tierney et al.
sources (be they natural or artificial) are present. The system resembles the Clark electrode, making use of hexacyanoferrate as oxidizing agent for the sulfide. All electrodes are located at the tip (diameter 30–50 µm) of a tube. Figure 24 shows the results for this sensor obtained during a flow-through experiment.

A summary of the development of biosensors for environmental applications was given by Renneberg and Gründig. They introduced a wide variety of potential analytes and sensors developed for their detection, but also stated that there are only a few systems for market-ready field applications owing to stability problems with the enzymes used. A paper dealing especially with the detection of organophosphorus pesticides was presented by Gibson et al.

### 4.1.4 Other Electrochemical Sensors

An overview of electrochemical sensors with solid polymer electrolytes which are of potential interest for environmental applications was given by Opekar and Štulík.

A promising approach for carbon dioxide sensing based on a coulometric device was proposed by Trapp et al.

Titration of CO₂ is done by cathodically produced hydroxide ions, whose excess after reaching the end-point is detected via a pH-sensitive electrode (which in fact means potentiometric sensing). The authors reported the possibility for detecting 200–20 000 ppm of carbon dioxide, which complies with the requirements in ambient sensing of this analyte. The sensor’s main drawback is its limited operational time.

A sensor system for the field measurement of redox potentials has been introduced by Teasdale et al. After discussing problems of electrode stability and calibration, they introduced a set-up with 15 platinum wire electrodes for the spatially resolved determination of estuary redox potential, be it in the water or at the water/sediment boundary layer. This measurand can be used as an indicator for pollution of the ecosystem being monitored. Additionally, concentration profiles over the boundary layer of analytes present both in water and in sediment are a topic of major scientific interest. Figures 25 and 26 show both the average redox potential profile and the iron concentration of a sediment site obtained with this apparatus.

### 4.2 Field Effect Devices

Lundström et al. gave an introduction to sensing via field effect devices and described a wide variety of (laboratory) applications. Some examples of ion-selective sensors (mostly pH) are given there and will not be discussed further in this article. Additionally, some gas-sensing applications are introduced, including analytes such as hydrogen, ethanol, hydrogen sulfide, ammonia,
FIELD-PORTABLE INSTRUMENTATION

Figure 27 Schematic set-up of an SGFET.

some hydrocarbon gases and carbon monoxide. Many of them are more within the range of laboratory methods than field testing. One exception is again the sensing of ozone: an SGFET coated with potassium iodide was used for its monitoring. The theory of gas FETs indicates that the electronic work function at an interface between the semiconductor and a layer different from it can be influenced by gas adsorption. The SGFET devices (Figure 27) make use of the interface between the lower side of the electrode and the air gap that can be found there. The response of this sensor during a field measurement in the Bavarian Alps compared with an industrial wet chemical ozone analyzer can be seen in Figure 28. The values obtained show excellent correlation between the data obtained by the sensor and the reference system, which again proves the suitability of chemosensors for environmental applications.

A pH-sensitive ISFET for the in-field detection of acid rain was introduced by Wakida et al. They found that tris(2-ethylhexyl)amine is an ideal gate material for the desired purpose, as is confirmed by the data depicted in Figure 29, where sensor results for field samples are compared with those obtained with a glass electrode.

Starodub et al. reported a sensor system based on electrolyte–insulator–semiconductor devices combined with multienzyme layers (containing, e.g. glucose oxidase, urease, cholinesterase) for the detection of toxic compounds, namely heavy metal ions and organophosphorus pesticides. Quantitative analysis is performed by the measurement of the residual enzyme activities after exposure to the analyte.

4.3 Optical Sensors

As already stated above, two types of optical sensing applications exist, namely those making use of chemically sensitive layers and the others relying directly on the optical properties of the analytes. Articles about the development of fiber-optic chemical sensors can be found elsewhere.

A field application for the detection of polycyclic aromatic hydrocarbon (PAH) compounds has been suggested. Six different analytes were investigated with a time-resolved fiber-optic fluorescence system with an optical pathlength of up to 50 m (for experimental apparatus, see Figure 30a and b). The qualitative information is obtained via both spectral and signal decay.
information (due to interaction with oxygen). The authors also examined the influence of humic acids, stating that despite their huge fluorescence signal at least a semiquantitative determination of the PAHs is easily possible. They can be detected down to the range of nanograms per liter over a fiber length of 50 m. Another system making use of fluorescence effects has been published by Frense et al. where changes in the fluorescence of algal chlorophyll is measured. As the cells react towards several herbicides and pesticides they can (after immobilization) be used for the detection of these analytes.

Fluorescence systems are widely used as a result of the method’s inherent advantages, which clearly outweigh the fact that only a limited number of analytes are accessible by this method: fluorescence spectrometry is usually a highly sensitive method allowing very low detection limits and the effects are very fast, can be measured accurately and often allow a discrimination between the analyte signal and the background, i.e. additional matrix substances.

A system consisting of three fibers for the detection of hydrocarbon vapors for pipeline leakage detection and tank, storage and transport monitoring has been introduced (see Figure 31). High-intensity Hg lamps and LEDs are used as optical sources. The nylon jacket and sometimes also the cladding of the sensing fiber are removed, thus exposing either directly the silica core or the silicone cladding directly exposed to the hydrocarbon analyte. The sensor works on quenching principles, therefore the light intensity in the reference fiber is much higher than that in the sensing fiber. Field data for the sensor response towards gasoline are given in Figure 32.

Larjava et al. introduced a Fourier transform infrared (FTIR) gas analyzer for the simultaneous determination of different industrial boiler exhaust gases. They reported the construction of a field testing device with integrated data evaluation for this purpose. Another system for the analysis of industrial exhaust gases is a fiber-optic laser spectrometer operating in the IR range.
for the detection of ammonia vapors being emitted from reactors to minimize NO\textsubscript{x} in exhaust gases.\cite{95} This system makes it possible to detect ammonia selectively even under conditions where many interfering gases such as water vapor are present. Another successful sensor based on NIR laser diodes for the determination of different ambient gases including humidity has been reported.\cite{96}

A hand-held fiber-optic system for the detection of organic solvents in water was introduced by Dickert et al.\cite{97} Here a diphenyl phthalide dye was embedded behind a gas-permeable membrane, which extracts the organic solvents from the water. The dye shows hypochromic effects and therefore the change in absorbance can be used to quantify analyte concentration. The whole system was included in a market-ready housing.

PAHs are a class of highly toxic substances occurring at all kinds of incomplete combustion processes. A possibility of their direct detection via fluorescence spectrometry by using molecularly imprinted polymers has been described.\cite{98} The sensors produced provide both good selectivity between different PAHs and low detection limits, as can be seen in Figures 33 and 34. Concentration limits for the fluorimetric measurements are down to 1 µg L\textsuperscript{-1} and even lower. Another system for the monitoring of anthropogenic compounds in groundwater

SOLID-STATE SENSORS FOR FIELD MEASUREMENTS OF GASES AND VAPORS

17

Figure 35 Response of sensors coated with different polymer layer heights.

under development was proposed by Leonard,\(^{(99)}\) who used fibers coated with a fluorescence dye.

Yang and Swager described a sensor for the detection of trinitrotoluene (TNT) vapor based on fluorescence quenching.\(^{(100)}\) As sensitive layers, fluorescent, shape-persistent porous pentiptycene polymers are used. Figure 35 shows the fluorescence quenching of the different analytes of interest for different film thicknesses, thus proving the analytical capabilities of this system.

A possibility for the detection of chlorine in air, based on a one-way sensor strip, was described by Ralfs and Heinze.\(^{(101)}\) The authors suggested o-toluidine embedded in a silicone–polycarbonate copolymer matrix with external reading in the visible and NIR region (350–1100 nm). The absorbance of the o-toluidine increases when ambient chlorine is present, and as a result analyte concentrations down to 0.05 ppm are detectable with this system. The low price makes it possible to use these sensors as discardable probes (the cost per piece is around US$ 0.1), thus highlighting the system’s suitability for fast analysis.

Another system based on NIR measurements was published by Zimmermann et al.\(^{(102)}\) Here optical fibers are coated with siloxane membranes suitable for the incorporation of nonpolar organic substances. These are extracted from aqueous media. Detection takes place by the absorption of evanescent NIR radiation. A great advantage is the fact that a long fiber can be used as a sensitive medium, therefore increasing sensitivity. A novel optical sensing system can be realized by surface-enhanced Raman scattering (SERS) taking place on colloidal gold or silver particles. An overview of this innovative technique, including some aspects of environmental analysis, was given by Vo-Dinh.\(^{(103)}\)

Lanthanide-enhanced fluorescence spectroscopy,\(^{(104)}\) where ligands influence a rare earth ion’s fluorescence behavior, has only recently been established as a potential sensing method. Fluorescence of these ions (often Eu\(^{3+}\)) is a comparably slow process (from 100 ns up to microseconds), so it can be separated from background signals fairly easily. This effect was utilized for the detection of nerve agents in water, where an optical sensor was constructed by molecularly imprinting a polymer with an Eu\(^{3+}\) complex containing a hydrolysis product of soman.\(^{(105)}\) The authors reported high sensitivity and selectivity, making field measurements possible. Sensors of this kind are not only of military interest but also show promise for pesticide sensing, as some organophosphorus nerve agents are closely related to agrochemical substances.

4.4 Mass-sensitive Sensors

Mass-sensitive devices have already been applied in both the gaseous and liquid phase. Additionally, both single sensors and arrays have been reported [for some fundamental aspects of the layer design for sorption sensor arrays, see Lau et al.\(^{(106)}\)]. Dickert et al.\(^{(107)}\) introduced QMB and SAW coatings based on mixtures of linear and globular molecules for the detection of diesel vapors. A sensor array based on six QMB devices with a resonance frequency of 10 MHz for the detection of organic vapors was described by Hierlemann et al.\(^{(108)}\) The sensors were coated with differently substituted polysiloxanes, widely applied as stationary phases in GC. The authors used 1-propanol, 2-propanol, tri- and tetrachloromethane, trichloroethylene and toluene and their mixtures as analytes. Different methods of data analysis were applied and compared with each other.

Another paper dealing with the separation of environmentally sensitive analytes was published by Dickert et al.\(^{(109)}\) In this case the detection of the chemically very

Figure 36 Selectivity pattern of mass-sensitive sensor array towards p-xylene and m-xylene. CAVS, VAS4S, two types of calix-resorcin-arenes; C\(_5\)-CDMe, permethylated diodo-octane-crosslinked beta-cyclodextrin; Epi-CDMe, permethylated epichlorhydrine-crosslinked beta-cyclodextrin.
similar isomers of xylene under different amounts of ambient humidity was the topic of interest. An array of four QMBs (principal frequency 10 MHz) was used, and the sensitive layer materials were cavitands instead of GC phases. Figures 36 and 37 present the different sensors’ responses to the analytes and Figure 38 shows the calibration and validation curves for the neural network used. The great advantage of this sensor system is its ability to discriminate between chemically very similar compounds (i.e. the three different isomers of xylene) and ambient humidity.

An important class of analytes for in-field sensing is chemical warfare agents and several sensor systems for their detection are under development. An SAW array containing 14 devices coated with different polymers such as fluoropolyl, poly(ethylenimine), ethyl cellulose and poly(epichlorohydrin) has been reported by Rose-Pehrsson et al. The entire device consists not only of the sensor array and the system of multi-component data evaluation but also of preconcentration tubes.

The optimization of a sensor array for the analysis of organic compounds in water has been published. The main importance of this system can be found in the monitoring of contaminants caused by ship-wrecking of tankers or other vessels. The authors introduced a wide variety of both sensor coatings and potential analytes using QMB thickness shear wave resonators.

5 CONCLUSION

Chemical sensors show a variety of inherent advantages giving them great potential for use in environmental analytical chemistry. These positive features include their ruggedness, the fact that the devices and systems are usually not too complicated (but nonetheless highly developed) analytical instruments, which can also be operated by non-professionally trained personnel, and their price. Some sensor systems have already proven to be powerful analytical tools in everyday use, e.g. the Figaro sensor and the lambda probe. The wide variety of methods (electronic, optic, mass-sensitive, etc.) and chemical interactions (host–guest, steric recognition, functional recognition, etc.) used open up an enormous range of potential measuring devices. Especially gas-sensing field applications have already been reported, but current research also deals extensively with sensor analyses in the liquid phase.

6 COMMERCIAL SENSORS

Although a wide variety of sensors (be they physical or chemical) for all kinds of measurands is commercially available, there are not many examples of market-ready chemosensors apart from the lambda probe and the Figaro sensor. An overview over commercially available multisensor systems (electronic noses) was given by Strike et al., including the composition of the respective sensor arrays.

A variety of sensors for atmospheric pollutants are based on amperometric detection. A typical cell is shown in Figure 39. These devices are offered for the detection of several oxides (sulfur, nitrogen, carbon)
and oxygen. Another company offering a wide variety of amperometric gas sensors is Sensoric,\(^{113}\) selling devices suitable for a range of analytes from atmospheric pollutants to compounds such as gaseous hydrides and phosgene.

A chemical nose containing six 10 MHz QMB resonators is sold by HKR Sensorsysteme.\(^{114}\) This array is built for the discrimination of complex species, the resonators being covered with six different GC layers. Potential analytes are all kinds of mixtures, e.g. present in food analysis. An electronic nose combining both tin dioxide and mass-sensitive devices is commercially available.\(^{115}\)

Food Analysis Techniques: Introduction

Robert J. McGorrin
Oregon State University, Corvallis, USA

1 INTRODUCTION

Food is a complex, heterogeneous mixture of vastly numerous and diverse biochemical substances. Food chemists are concerned with the composition and properties of food products, beverages, confections, and flavors and the chemical and physical changes they undergo during post-harvest handling, processing, storage, and preparation. Measuring the quality, safety, sensory properties, nutrition, and stability of food products is the primary concern of analytical chemists working within the food processing industry, and in academic and government laboratories affiliated with food programs. The Nutrition Labeling and Education Act of 1990 (NLEA) set new labeling requirements for all packaged foods sold in the USA \(^1\) which often necessitates the determination of both macro food components and trace nutrients by analytical techniques. Besides quality assurance, the goals of food analysis may be directed towards basic research (healthy food ingredients, bioactive compounds for disease prevention) or product development (convenient preparation, better tasting).

The range of food products which may require analysis encompasses foods which may be respiring (meats, fruits and vegetables) but not growing, or others capable of growth (seeds, eggs). Food products are prepared from disrupted components such as flour; fruit and vegetable purees and juices; and isolated carbohydrates, proteins, and vegetable oils. Dairy chemists utilize milk as a feedstock for production of cheese and cultured dairy products, which require analysis to ascertain the fermentation endpoints for optimum flavor and texture. Foods are usually highly hydrated, but their moisture contents may range from more than 95 percent to less than 4 percent.

Appearance, color, flavor, and texture are critical aspects for the sensory quality of foods. Alternatively the instability of foods, which limits their shelf life, can be initiated by chemical reactions, enzymatic reactions, or physical forces. Analysis of the degree of emulsification or moisture content, for example, may allow a prediction of the shelf life limit to be made for a salad dressing or a potato chip snack, respectively. Changes in texture are the result of toughening or softening, loss or gain in solubility or water-holding capacity. Flavor alteration may result from development of oxidative rancidity, undesirable browning reactions, or desirable compounds produced through cooking. Typical color changes include darkening or bleaching and the development of desirable colors, or production of off-colors. In most cases, food assays have been developed to enable measurement of food product attributes, depending on the specific application. Precise characterization of foods enables new product development and quality control, while troubleshooting product problems and customer complaints.

2 ANALYTICAL CHALLENGES FOR FOOD ASSAYS

The isolation and measurement of individual chemical species in food systems usually poses a difficult challenge. Despite the availability of modern techniques of separation and identification, such as gas chromatography/mass spectrometry (GC/MS), high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS), etc., rarely is it possible to load a syringe with a food sample, and directly inject it into an analytical instrument to obtain a sensible result! Because of the diversity of food products and the variety of analytical methods depending on the intended application, procedures for preparation of different food sample categories need to be developed, evaluated, and collaboratively studied among various laboratories as an integral part of any analytical method.

3 SAMPLE PREPARATION

Sample preparation and extraction remain among the most time-consuming and error-prone steps in the food analysis process. However they are critical procedures because food scientists need to isolate and concentrate a wide range of analytes from complex and varied matrices.

The chemical analysis of foods and raw materials is a multistep process with three key stages: sampling,
homogenization, and sample preparation. Sampling involves the procurement of a representative sample for the laboratory. The sampling process may require dividing a food into edible and nonedible portions, and making selections based on the analytical objective, e.g. selecting only for ripened rather than over-ripe fruit, or for baked goods with correct degree of browning. A homogeneous composited sample is prepared by chopping or grinding, followed by blending or mixing. This ensures that a sample is obtained which is representative of the overall food mixture, from which several subsamples can be taken (e.g. imagine sampling a pizza which contains mushroom, sausage, and green pepper components). Care must be taken to avoid contaminating the sample or exposing it to excessive heat, which can cause loss of volatile flavor components or accelerate decomposition of labile food components such as vitamins. Finally, sample preparation is the physical and chemical manipulation of the test portion prior to analytical measurement. Sample preparation typically involves pH adjustment, extraction with organic solvents, solid-phase extraction, cleanup (filtration, liquid–liquid partitioning), and concentration. As an alternative, headspace concentration may be performed to capture volatile components as an alternative to solvent extraction. In this encyclopedia, food sample preparation topics are discussed in subsequent articles by M.J. Lichon, Sample Preparation for Food Analysis, General; and A. Chaintreau, Sample Preparation, Headspace Techniques.

New instrumental techniques that are easily automated and integrated with other analytical systems are key to productivity and data integrity for many laboratories. Automated instruments are helping to drive interest in improved sample extraction and preparation methods. These techniques are not only environmentally sound, because they incorporate low-volume or solvent-free extractions, but in most cases, they can increase the efficiency of the extraction. Examples include supercritical fluid extraction, accelerated solvent extraction, solid-phase extraction, solid-phase microextraction (SPME), and thermal desorption (TDS). Discussion of these instrumental methods can be found in the article by M. Rothaupt, Sample Preparation Analytical Techniques for Food. Modular systems are now readily available that automate these procedures and bridge them to analytical instruments, such as gas chromatography (GC), GC/MS or high-performance liquid chromatography (HPLC).

4 MACROCOMPONENT ANALYSES

Proximate analyses (fat, protein, moisture, carbohydrate, and ash contents) have been typically performed using classical wet chemistry methods to ensure the suitability of food products. New developments in instrumental techniques are providing rapid, automated alternatives to classical methods. Current regulatory requirements for food manufacture oblige not just the analysis of fat content, but also the quality of the fat, i.e. saturated, monounsaturated, polyunsaturated, monoglycerides, diglycerides, cholesterol, etc. Classical total protein determinations were historically based on nitrogen content (the Kjeldahl technique); however modern electrophoretic and chromatographic methods are being developed which enable rapid and specific amino acid and peptide assays. Bulk carbohydrate values are required to be listed as specific sugars: simple, complex, starch, dietary fiber, and crude fiber. Moisture content has been redefined to specify water as being “free”, “bound”, or “hydrated”, and all of these modes require a specific analytical measurement. These fundamental aspects of food analysis are described in subsequent articles by S.S. Nielsen, Proximate Assays in Food Analysis; D. Marini, Lipid Analyses in Food; S. Dierckx, K. Boeve, J. Van Camp, and A. Huygenbaert, Proteins, Peptides, and Amino Acids Analysis in Food; H.N. Englyst, Starch Analysis in Food; H.N. Englyst, M.E. Quigley, and G.J. Hudson, Dietary Fiber Analysis as Non-starch Polysaccharides; and D. Reid, Water Determination in Food.

HPLC is a very powerful and versatile technique for analyzing and purifying biomolecules, and consequently is a well-established mode for food and beverage analysis. Ongoing advances in column supports, bonding chemistry, and packing materials have enabled increased speed and efficient separation of a wide range of organic and inorganic food analytes at low parts per million and high parts per billion levels. Related column techniques that involve separation by either ionic mobile phases or charged fields are ion chromatography (IC) and capillary electrophoresis (CE) respectively. Typical food analytes quantified by these techniques include sugars, aspartame, phospholipids, vitamins, caffeine, organic acids, ionic species, peptides, and proteins. More sensitive fluorescence detectors for HPLC instruments enable lower limits of detection for vitamins, proteins, aspartame, and mycotoxins. In this encyclopedia, these topics are covered in articles by L.M.L. Nollet, Liquid Chromatography in Food Analysis; P.F. Cancalon, Electrophoresis and Isoelectric Focusing in Food Analysis; and S. Nakai and Y. Horimoto, Fluorescence Spectroscopy in Food Analysis.

Spectroscopic techniques are highly desirable for analysis of food macrocomponents because they often require minimal sample preparation, provide rapid analysis, and have the potential to run multiple tests on a single sample. These advantages particularly apply to nuclear magnetic resonance (NMR), infrared, and near-infrared...
spectroscopy. The latter technique is routinely used as a quality assurance tool to determine compositional and functional analysis of food ingredients, process intermediates, and finished products. In this encyclopedia, these instrumental methods are discussed by J.S. de Ropp and M.J. McCarthy, \textit{Nuclear Magnetic Resonance in the Analysis of Foodstuffs and Plant Materials}; R. Mehrotra, \textit{Atomic Spectroscopy in Food Analysis}; and B.G. Osborne, \textit{Near-infrared Spectroscopy in Food Analysis}.

5 MICROCOMPONENT ANALYSES

Volatile compounds are among the samples most often analyzed in foods, flavors, and aroma systems. The combination GC/MS has been used since the 1960s to characterize flavor mixtures. More recent developments in capillary column technology and integrated headspace sampling systems have shortened the assay time, and increased limits of detection for potent flavor components. This topic is discussed by Y. Chen and C.-T. Ho, \textit{Flavor Analysis in Food}.

Additional trace components in foods include colorants, pigments, vitamins and minerals. Recent interest in so-called “functional foods”, which impart health benefits beyond basic nutrition, relies on the development of new assays with increased sensitivity and specificity to measure efficacious phytochemical components in foods. In this encyclopedia, techniques for analysis of vitamins are described by L. Ye and R.R. Eitenmiller, \textit{Vitamins Analysis in Food}.

Atomic spectroscopic methods including atomic absorption, atomic emission, and elemental mass spectrometry are routinely used to measure elements (e.g. sodium and calcium) and heavy metals (e.g. lead and cadmium) in food products. Inductively coupled plasma mass spectrometry (ICP/MS) offers the advantage of providing simultaneous multielement measurement, which facilitates analysis of the large numbers of elements in food samples. For further discussion, see S.A. Baker and N.J. Miller-Ihli, \textit{Atomic Spectroscopy in Food Analysis}.

6 PHYSICAL METHODS

Various physical properties are important to measure and characterize attributes related to food texture, viscosity, emulsion stability, and particle size. “Texture” is typically associated with solid or semi-solid foods (for example cream cheese, chocolate, jelly) and can be measured using rheological tests which qualify shear rate, compression, fracturability, and viscoelastic properties. However, fluid foods such as sugar syrups, vegetable oils, and wines can also be characterized by these techniques. Measurement and understanding of physical attributes enables control and adjustment of food sensory properties including “mouthfeel”, crispness, stickiness, chewiness, and creaminess. Instruments which measure these properties include viscometers, pressure/force transducers (Instron), and rheometers. These tools facilitate food process uniformity, standardization, and quality assurance and are fully discussed in the section by M.A. Rao, \textit{Viscosity of Food: Measurement and Application}.

The measurement of gas, liquid, solid, or botanical “particles” in foods relates to quantifying their particle size distribution. Examples of applications for particle size analysis include control of grittiness from lactose crystals in ice cream, creaminess of margarine emulsions related to water droplet size, and separation stability of salad dressings due to oil droplet size and distribution in the continuous phase. Size distribution of powdered food ingredients such as starches, spray-dried milk, or encapsulated flavors may relate to speed of water dispersion or perceived grittiness in the mouth. Several instrumental techniques are used, which include microscopy, laser light scattering, field-flow fractionation, NMR, and ultrasonic spectroscopy. Particle size techniques are further described in the article by M.M. Robins, \textit{Particle Size Analysis in Food}.

7 SPECIAL APPLICATIONS

Enzymes, microbes and antibodies can be used as biosensors to rapidly measure the presence of amylases or proteases in foods, which can lead to starch thinning or bitter flavors, respectively. Enzyme-linked assays have been used to measure vitamins, antibiotic residues, microbial toxins, various sugars, ethanol, and carbon dioxide. In certain cases, enzyme activity assays are useful food safety probes to measure whether adequate processing of a food product has been achieved. This is further discussed by J.R. Powers, \textit{Enzyme Analysis and Bioassays in Food Analysis}.

Analytical techniques have been developed for determination of authenticity of suspect food products and ingredients, where price differentials prompt economic fraud. Modern examples include substitution of corn syrup for honey; organic acids and sugars for apple juice; and benzaldehyde for almond extract. Combinations of chromatographic, NMR, isotopic, and enzyme-linked methods have been used to screen suspected food ingredients. (See E. Wilhelmsen, \textit{Adulteration Determination}).

Analytical measurement of toxicological residues in foods including pesticides and aflatoxins is described by M. Volante and P. Branca, \textit{Pesticides, Mycotoxins and Residues Analysis in Food}. Techniques discussed include
chromatographic, spectrographic, and immunochemical methods for assaying these compound classes.

Modern analytical instrumental techniques, when applied as probes for basic research, enable interactions to be studied with in vivo situations. As an example, two-dimensional nuclear magnetic resonance (2-D NMR) techniques have been applied to probe the metabolic processes in plants, and the interaction between plants and soils. This enables in vivo measurements of metabolite concentrations, enzyme kinetics, stable isotope tracers for biochemical pathway elucidation, and structural characterization of organic matter. Recent advances are described elsewhere in this encyclopedia by T.W.-M. Fan and A.N. Lane, *Nuclear Magnetic Resonance in Analysis of Plant Soil Environments*.

Adulteration Determination

Eric C. Wilhelmsen
Wilhelmsen Consulting, Milpitas, USA

1 Introduction

1 INTRODUCTION

The history of food authentication closely parallels the early history of food chemistry. Sadly, as people gained a better understanding of the composition of foods, this information was used to improve the formulas for adulterating food. However, early efforts in food chemistry also allowed detection of fraud and adulteration. It is probable that the war between authentication practitioners and those who would deceive the buyer is much older than the historical record.

It is likely that human greed has prompted adulteration for almost as long as food has been traded. Watered wine was familiar to the writers of the Old Testament of the Bible. A stele of King Hummurabi of Babylon from around 1750 BC prohibits the sale of weak and overpriced beer. (1) The extensive trade of Roman times was not without its problems, including complaints about misbranded wine. (2) The extensive trade of Roman times was not without its problems, including complaints about misbranded wine. (3) From the seventeenth century forward the record becomes more extensive. For some, Frederick Accum’s publication A Treatise on Adulterations of Food was an important turning point. It aroused concern and indignation about the quality and safety of the food supply. A modern textbook (4) cites Accum’s treatise and lists most of the following adulterations as not uncommon from this period:

- Annatto – Turmeric, rye, barley, wheat flour, calcium sulfate and carbonate, salt, and Venetian red (ferric oxide, which in turn was sometimes adulterated with red lead and copper) were used as adulterants;

Determining adulteration in food is accomplished by comparing analytical data with historical or control data. Without a proper reference set, the determination of adulteration is impossible. Adulteration is best shown by detecting a foreign component that is characteristic of a specific adulterant. Sometimes it is necessary to use deviations in a parameter, but typically these approaches are less sensitive owing to the natural variation in food. Often practitioners are interested in the more difficult converse, that is, authentication of a product or ingredient. In practice, authenticating a product or ingredient is equivalent to not finding any adulteration. Clearly, authentication is a negative, the absence of adulteration. It can never be entirely proven. The quality of a determination of authenticity is clearly linked to number and types of tests performed. The decision not to perform a test that yields additional information increases the potential of erroneously accepting a sample.

This proof of the negative challenge has led to competition between the practitioners of authentication and those who would adulterate their products or ingredients. This competition is readily apparent. Each time a useful new method has been introduced, previously undetected adulterations have surfaced. Unfortunately, the new methods generally do not supersede older methods and represent additional authentication costs. Fortunately, the vast majority of the food industry is not involved and generally cooperates in policing the marketplace.
Beer – Watering was undoubtedly occurring. In addition, pigments such as vermillion (α-mercury sulfide), ocher (mixtures of metallic oxides especially iron and clay) and turmeric were used.

Milk – The addition of water was the main form of adulteration, hence the name for the village water pump, the “black cow”; other common adulterants included chalk, starch, turmeric for color, gums, and soda. Occasional adulterants included gelatin, dextrin, glucose, preservatives (borax, boric acid, salicylic acid, sodium salicylate, potassium nitrate, sodium fluoride, and benzoate), and colors including annatto, saffron, caramel, and some sulfonated dyes.

Pepper, black – This product was adulterated with many foreign substances including gravel, leaves, twigs, stalks, pepper dust, linseed meal, and plants other than pepper.

Pepper, cayenne – To restore color lost from bleaching by light, pigments such as vermillion (α-mercury sulfide), ocher (mixtures of metallic oxides especially iron and clay) and turmeric were used.

Essential oils – Oil of turpentine, other oils, and alcohol;

Vinegar – Sulfuric acid;

Lemon juice – Sulfuric and other acids;

Coffee – Roasted grains, occasionally roasted carrots or scorched beans and peas; also baked horse liver;

Tea – Spent, redried leaves and leaves of other plants;

Milk – The addition of water was the main form of adulteration, hence the name for the village water pump, the “black cow”; other common adulterants included chalk, starch, turmeric for color, gums, and soda. Occasional adulterants included gelatin, dextrin, glucose, preservatives (borax, boric acid, salicylic acid, sodium salicylate, potassium nitrate, sodium fluoride, and benzoate), and colors including annatto, saffron, caramel, and some sulfonated dyes.

Beer – Watering was undoubtedly occurring. In addition, “Black extract”, a water extract of the poisonous berries of Cocculus indicus was apparently added to impart flavor, narcotic properties, and toxicity to the beverage;

Wine – Various colorants, flavors, aging agents, preservatives and antacids were added;

Sugar – Sand, dust, lime, pulp and coloring matters were added;

Butter – Excessive salt and water, potato flour, and curds;

Chocolate – Starch, ground sea biscuits, tallow, brick dust, ocher, Venetian red, and potato flour;

Bread – Alum and flour made from products other than wheat;

Confectionery products – Colorants containing lead and arsenic.

Once the seriousness of the adulteration problems became evident in the 1800s, many forces were marshaled to remedy the situation. Legislation was passed. Scientists focused their talents on food chemistry. These forces greatly improved the situation and continue to operate today, but adulteration has still not been eliminated.

In 1922 the United States Department of Agriculture investigated a claim that a chocolate coating was made by illegal substitution of coconut oil for cocoa butter and milk fat. In 1923, convictions were handed down in Federal Court in the United States for adulterating olive oil with peanut oil. In 1926, a butter fraud was detected where a low-grade butter, lard and buttermilk mixture was sold as butter. In 1936, sardines packed in “olive oil” were found to be packed in mixed oil. In 1938, a Nebraska firm shipped butter low in butterfat. The list goes on and on.

Today, food adulteration is primarily economic. Consumers purchase a product and receive something else of lesser value, usually a mixture of the authentic product and something to extend it. Examples include corn syrup in honey, hydrolyzed inulin in apple juice, grapefruit juice in orange juice, and other food oils in olive oil. These substitutions are easy to detect with modern methods. More examples and details are included in section 3.4 below. Sadly, one can only wonder about what types of deception are still defeating the screening methods.

2 REGULATORY RESPONSES

Regulatory response is usually started by passing a law or act. Such laws allow various types of enforcement action including standards, definitions and test procedures to be defined. Around the world, different nations have taken different approaches. Sometimes these approaches are viewed as nontax trade barriers because they are too restrictive or are arbitrary. These barriers classify product from other geographic regions as out-of-specification. Such barriers are mentioned here only because their expressed purpose is to prevent adulteration.

The first food laws in the United Kingdom were enacted in 1860 and 1875. Canada enacted its first in 1875. The first comprehensive food law in the United States was passed in 1906. This law prohibited the use of certain harmful chemicals in foods and prohibited the interstate commerce of misbranded or adulterated foods. In the United States, concerns about adulteration and false health claims led to passing the Food, Drug and Cosmetic Act (FDCA) in 1938, which was later revised in 1958 with the Food Additives Amendment of the Federal FDCA. This amendment documented the principle of establishing the safety of chemicals before allowing use, which is now a widely accepted practice all over the world. In Europe, the European Union is working towards a harmonized set of regulations. This is still very much a work in progress. Internationally, Codex Alimentarius has developed more than 220 commodity standards, 40 codes of practice and limits for more than 500 food additives. Both these organizations are moving toward more horizontal regulations that cut across commodities. These laws, acts and other forms of legislation provide...
ADULTERATION DETERMINATION

3 MODERN DEFINITIONS AND TYPES OF ADULTERATION

For the purposes of this article, food will be considered to be adulterated if:

- Any valuable constituent has been in whole or in part omitted;
- Any substance has been substituted wholly or in part therefore;
- Damage or inferiority has been concealed in any manner; or
- Any substance has been added thereto or mixed therewith so as to increase its bulk or weight or reduce its quality or strength, or make it appear better or of greater value than it is.

This definition is based on the United States FDCA but has general applicability. The vast majority of this article focuses on the procedures and practices used to detect one or more of these criteria.

3.1 Misbranding

Misbranding comes in many forms. It is the mislabeling of a product. It is one of the faults associated with the sale and distribution of an adulterated product. Properly labeled, many misbranded products would be legal but they might lack the consumer appeal of the mislabeled product. Declaring an inferior grade of olive oil to be extra virgin is an example of misbranding that would fall in the third definition of adulteration. To label a product 100% juice that is in reality 10% hydrolyzed inulin syrup (HIS) is another example of misbranding. This type of misbranding would fall into the second class of adulteration, where something is added. Any time a product does not conform to the information on the label, misbranding has occurred.

When a food processor purchases an ingredient from a supplier, it is generally purchased with the intent to use it in a product where it will be identified on the ingredient list as the material purchased. If a food processor buys an ingredient such as apple juice concentrate from a supplier, it is usually with the expectation that they will be able to use the same name on their ingredient list. If the concentrate in question is not pure apple juice concentrate, any product made from the concentrate would be misbranded because it misidentifies the ingredient. Therefore a user can be guilty of misbranding with no knowledge of the infraction. However, in most of the world, intent would be considered before invoking criminal penalties.

Misbranding also extends to ingredients that are misnamed. Such products fit into the third class of adulterated foods where inferiority is being concealed.

general guidance for the most part and yield definitions such as those discussed in the next section.

Sometimes organizations develop definitions. For example in the United States, the Code of Federal Regulations included standards of identity that define the preparation and composition of some products and ingredients. If a product does not conform to this specific definition, it is not the product in question. Non-conforming products need to be labeled carefully to avoid misbranding.

In some cases this legislation has led to more specific enforcement tools. The German Richterwerte und Schwankungsbreiten bestimmter Kennzahlen (RSK) values are a specific example. These values are intended as guidelines for verifying the nonadulteration of fruit juices and other products produced from them. The RSK values are intended to include the natural variation in these commodities. In practice, there continues to be discussion about what was included and not included in the original data. The Dutch and Japanese have also developed their own reference values.

In some cases, these reference values have been supported by specific methods. Around the world, different organizations have supplied certified methods. AOAC (Association of Official Analytical Chemists) International is one certifying organization. The Technical Committee for Juice and Juice Products (TCJJP) has submitted juice authentication methods to AOAC through its membership. In Europe the International Federation of Fruit Juice Producers has developed a compendium of certified methods.

At the bottom line, a practitioner seeking to authenticate a food product must understand his/her goal. The requirements to prove adulteration legally vary with country. The decision to buy or not buy a lot of a commodity can require a lower level of proof than required to obtain judgement in court or gain a criminal conviction. In the United States, federal prosecutors have been successful in prosecuting some cases. For example, they obtained:

- A $100,000 fine and 5 year prison sentence for the former president and chief executive officer of an orange juice company that put more than 40 million gallons of adulterated orange juice on the United States market over 11 years.
- Fines and forfeitures totaling $120,000 for a seafood company and two of its principals for adding water to scallops to increase their net weight and thus net profits since scallops are priced by weight.
- A $2.18 million fine for an established baby-food manufacturer for selling a product labeled “100 percent” apple juice but which actually contained only sugars, water, and flavorings.
but are otherwise not very interesting from an analytical point of view. To illustrate this point we can consider a set of examples. There is a growing interest in healthy and natural foods. Sugar and other traditional sweeteners such as corn syrup are undesirable. To overcome these objections, formulators have normally used fruit juice concentrates, rice syrup and other sweeteners. More recently, there have been a number of new sweetening ingredients that are breaking new ground and finding acceptance in the marketplace. Some examples include “agave nectar”, a fructose syrup made from the root of the agave plant which has no juice component, “evaporated cane juice”, a partially refined sucrose from sugar cane that is not a juice product, and “a natural extract from corn and barley malt”, an exotic form of glucose syrup. Given that these ingredients have been purchased in good faith by the processors who labeled them as the ingredients they purchased, are the producers guilty of misbranding? Potentially yes, if some regulatory agency such as the United States Food and Drug Administration determines that these ingredients were improperly labeled when they were sold. For these examples, no authoritative statement has been made, so a processor needs to decide whether the names being used are appropriate. If these names are challenged by a regulatory authority, the marketing advantage obtained by using these exotic names could be lost, with other damaging consequences. From the analytical perspective of determining adulteration in foods, the problems of misnaming a food and the resulting misbranding are not particularly germane. Such problems are for lawyers and regulators who are attempting to maintain a level playing field where consumers can purchase products that are fairly labeled.

Misbranding and adulteration do not extend to the problem of quality. Ginseng root is reported to lack potency until it is over 6-years old. However, ginseng powder in the absence of a standard of identity or other regulatory definition would refer to the powder from Panax giseng, irrespective of potency. At present, methodologies are still in development for authenticating botanicals, but there are many problems in dealing with them. However, in the broadest sense, important and valuable components are missing, so this ginseng could be considered adulterated. Many other products could lack valuable components as well. Processed orange juice will have less vitamin C than fresh orange juice. Yet this loss of vitamin C is not considered a form of adulteration.

3.2 Economic Adulteration

At present this is the most significant class of adulteration problems. It can involve either removing or diluting components, or it can involve adding components. In most cases misbranding also occurs. The key feature of economic adulteration is the use of an ingredient of lesser value or cost than the authentic product. This provides a greater volume of product that was cheaper to produce and can still be sold at an equivalent or almost equivalent price.

Water is the adulterant of choice. It is generally cheaper than any food product. A slight dilution can provide a handsome increase in the profit margin of a food company if their customers do not notice the reduction in component concentration. Water has been added to many beverage products to increase the volume. Sometimes other components are added to mask the addition of water. Various sugars and organic acids can be used to mask water addition, depending on the product.

The general rule for detecting economic adulteration is to monitor an expensive component that is present in consistent amounts. Monitoring specific anthocyanins is an appropriate way to detect the addition of plum juice in dark cherry juice. The presence of naringin in orange juice usually points to the addition of grapefruit juice. The postmanufacturing addition of orange pulp wash is another form of economic adulteration. The legal status of this practice varies from location to location. However, no jurisdiction considers pulp wash to be synonymous with orange juice.

Economic adulteration can also involve removing components. It is possible to refine a product to such an extent that it becomes something else. For example low-quality grape or apple juice can be treated extensively with activated carbon or ion-exchange resins. These treated juices will become colorless and almost flavorless sugar solutions. The organic acids, the polyphenols and some minerals will have been removed. The materials will no longer be juice. These materials would make a very good base for a fruit-flavored punch. How far down this path should a processor be allowed to go and still call the product a juice? Enforcement in this area is still very difficult.

Economic adulterations generally pose no health risk to the consumers. They do, however, distort the marketplace. A reputable processor cannot compete when a competitor can get 10% more profit per unit of production by selling adulterated product. The lack of health risk makes obtaining resources to investigate economic adulteration hard to justify. Government regulators are generally focused on food safety issues. Food processors are reluctant to spend money to monitor the purity and quality of ingredients if there is only a limited enforcement threat.

A new motivation has arisen to influence United States processors. Plaintiff lawyers have become more aggressive in pursuing class action suits on behalf of the consumers who have been deceived by one or more food
companies. The adverse publicity associated with the courts certifying a plaintiff class has generally prompted companies to settle out of court. Such actions are often pursued after the news media break a story about some adulteration or other food problem.

### 3.3 Filth and Other Foreign Substances as Adulteration

Although clearly a form of adulteration, filth and other foreign substances are much less significant in today’s marketplace. The adulterations of the 1800s discussed above included more of these types of problem. Such problems are generally characteristic of less developed marketplaces, where accepted norms of production and quality are still developing. These conditions prevail in the markets for many botanicals and other herbs used in dietary supplements. An early study on authenticating coffee seems appropriate to recall. The work of Arthur Hill Hassell on coffee in 1850 is cited as an example of using a microscope, an innovation in his day, to detect adulterants such as chicory, roasted wheat, and burnt sugar in coffee. Perhaps purchasers of botanicals should apply the same direct approach.

When other foreign substances are discussed, economic adulterants are generally not considered. Two recent examples will serve to illustrate the distinction. In 1981 in Spain, industrial grade rapeseed oil was substituted for edible olive oil. In this incident, more than 20,000 people were made ill and as many as 800 people died. The work of Arthur Hill Hassell on coffee in 1850 is cited as an example of using a microscope, an innovation in his day, to detect adulterants such as chicory, roasted wheat, and burnt sugar in coffee. Perhaps purchasers of botanicals should apply the same direct approach.

In the late 1980s, low juice levels were detected in cranberry juice cocktails. Finished products did not contain the necessary 25% juice. The detection of additional citric and malic acids and of grape skin pigments was pivotal. Some samples were determined to have as little as 5% juice. In a case that still plagues the Gerber Products Company, who had absolutely no involvement, another major baby-food provider was detected selling artificial apple juice in 1988. The baby-food manufacturer did not actually make the artificial product. They purchased it as a concentrate from another manufacturer. Nevertheless, substantial fines and criminal penalties were imposed. This artificial product lacked components such as chlorogenic acid. It also contained D-malic acid from the use of racemic malic acid in the formulation.

### 3.4 Modern Examples

Adulteration continues to be a problem. Most of the food industry seems content to produce authentic food, but each time a significantly new methodology is applied to detecting adulteration in food, a new scandal is uncovered. Often the companies hurt most are the honest competitors who did not even profit from the adulteration. It should be noted that generally all the facts do not emerge when these events are uncovered. Often, there are different perspectives. No matter how carefully examples are presented, some bias will occur.

Cane sugar and corn syrup have a long history of use in foods. Prior to the application of stable isotope ratio analysis (SIRA), these materials were more difficult to detect in food products where they did not belong. In practice it is possible to determine whether a product contains sugar produced by Calvin cycle plants (C-3), by Hatch–Slack (C-4) plants or by a plant using the unusual Crassulacean acid metabolism (CAM). This methodology detected substantial adulteration of orange juice, apple juice, honey and maple syrup with these inexpensive corn and cane sweeteners in the 1970s and 1980s.

In the mid-1980s, a company was producing a 100% juice product relying on a mixed fruit concentrate as a major component. Unfortunately, it eventually came out that a major component of the mixed fruit concentrate was a fruit syrup made by strong ion-exchange treatment of a low-quality juice product. This low-cost component provided a substantial and unfair cost advantage. This cost advantage prompted the investigation by competitors that led to the discovery of the nonjuice component.

In the late 1980s, low juice levels were detected in cranberry juice cocktails. Finished products did not contain the necessary 25% juice. The detection of additional citric and malic acids and of grape skin pigments was pivotal. Some samples were determined to have as little as 5% juice.

In a case that still plagues the Gerber Products Company, who had absolutely no involvement, another major baby-food provider was detected selling artificial apple juice in 1988. The baby-food manufacturer did not actually make the artificial product. They purchased it as a concentrate from another manufacturer. Nevertheless, substantial fines and criminal penalties were imposed. This artificial product lacked components such as chlorogenic acid. It also contained D-malic acid from the use of racemic malic acid in the formulation.

In the mid-1990s a family-owned honey and syrup making operation netted $500,000 from its bogus products. This company was investigated because consumers complained that the products did not taste authentic.

In late 1995 and 1996, apple juice concentrate was entering the United States that contained HIS in the place of some of the apple juice concentrate. While the product, which is a high-fructose syrup, was not considered to be a health risk, it did prompt sampling and testing nationwide. Many companies voluntarily pulled product from stores shelves. Class action litigation followed. The HIS was detected with a capillary GC (gas chromatography) method that had not yet received great acceptance.
In 1997 at the Food Authenticity – Issues and Methodologies (FAIM) workshop in La Baule, France, a wide range of adulteration concerns were raised. These included:

- inappropriate strains of bacteria in cultured dairy products claiming to contain special probiotic species;
- nonmilk fat in butter;
- the use of ultrafiltration to increase the yield of cheese through the inclusion of whey proteins;
- cheeses made from milk of different species than claimed (e.g. goat cheese including cow’s milk);
- soft wheat adulteration of durum wheat semolina and pasta;
- orange juice adulteration with other sugars, other fruit, colors, flavors and pulpwash;
- beet sugar in honey;
- virgin olive oil contaminated with other refined oils such as sunflower oil;
- mixing of species within meat products;
- mislabeling of fish species.

In 1998 and 1999, juice drink products were observed to contain less than their declared juice content. Other drinks have contained undeclared juices in lieu of the declared ingredients. Nut confections have been found to contain traces of undeclared nut meats from other species and have apparently caused severe reactions and death.

The war goes on between authenticators and those individuals who would profit through deception. Authentication practitioners continue to seek newer and more efficient methods. Others seek new ways to squeeze extra profits out of their sales, even if the customer does not receive quite the product they wanted. Unfortunately, as in most wars, it is the innocent bystanders who suffer most. When an adulteration scandal breaks, the whole industry is suspect. The ethical producers are painted with the same brush, lose good will, and generally lose revenues.

4 STRATEGIES FOR DETERMINING ADULTERATION

All strategies for determining adulteration rely on comparing an unknown to a body of data. Such comparisons can be as simple as detecting a foreign component, to as complex as matching spectra to a model adulterated sample. One of the biggest challenges in this process is selecting the data for comparison. If this control group is inappropriate, any determinations are likely to be in error.

There are many recurring themes in adulteration. The chief adulterants are water, sweeteners, or inexpensive cousins. The choice of water is obvious. Dilution of liquid products like milk or juice is an old problem. Sweeteners add bulk and are generally less expensive than other food components. Today, a creative formulator has many sweetener choices. One is generally similar in composition to the product that is to be extended. And finally, a product may have a distant cousin that is much less expensive. Grapefruit dilution of orange juice is an obvious example. Given the recurring themes in adulteration, it should not be surprising that there are recurring themes in determining adulteration. The next five subsections examine some of these themes.

The peer-reviewed literature contains a significant amount of compositional data but not all of it is relevant to authenticating food products. This data requires work to extract but is clearly a reasonable place to start. When one must deal in many commodities, it may be necessary to rely on the efforts of others to collect this data. Generally, it is even more prohibitive to generate one’s own data. There are references that tabulate the composition of various food products individually. There are some that tabulate the results for a variety of commodities. Are these results valid? Were the test materials authentic? Do they represent the population of interest? Every practitioner must determine whether a specific data set is appropriate for each determination of authenticity.

In many parts of the world various food compendiums are accepted as a regulatory standard for juice. The previously mentioned RSK values are one such example. The values of the Association Francaise de Normalization and the Criteria for Authenticity in the Netherlands are two more. These compendiums are all of limited value because they do not present the data for individual samples and only present summary data such as the mean and some measure of dispersion. Without actual case-by-case data, many correlations are lost, greatly reducing the information that can be extracted regarding the composition of these commodities. The normative database of the TCJJP is an attempt to overcome this limitation.

There is a final problem associated with selecting data for comparison. How can this data be validated? What is the true value for any compositional parameter? This is a vexing problem when various databases disagree. It is complicated further by the potential for data from adulterated samples to be included in various compendiums. If one orders a simple commodity like apple juice, how many different products are likely to be received? Which ones should be used to generate data?

4.1 Specific Marker for an Adulterant

This is the simplest case and a theme that appears often. Typically there is a marker compound that does
not belong in the food product being tested. This marker is a well-documented constituent of a potential adulterant. This approach assumes knowledge about the food product. The comparison relies on the knowledge that the marker is not found in the food product. Given that the marker does not belong in the food, it is expected never to be present at levels at or above the detection limit. Therefore any confirmed detection is indicative of adulteration. The need for confirmation is related entirely to the expected action of the practitioner’s client. Litigation will demand a higher standard of proof than a decision not to buy.

Interpretation of these specific markers is straightforward. If the marker is above the level of quantitation it can be used to estimate the level of adulteration based on a typical concentration in the adulterant. Clearly, other markers and components might be desirable to build a stronger case for litigation, but one well-chosen marker should be enough to establish that the product has been modified.

HPLC (high-performance liquid chromatography) analysis of the anthocyanin pigments in a product can provide this type of evidence. The anthocyanins of grape and grape-skin extracts are very different from those found in strawberry. In strawberry one finds anthocyanins based on the anthocyanidins, pelargonidin and a little cyanidin. The anthocyanidins are the aglycones obtained after the removal of the sugar side chains from the anthocyanins. In contrast, grape products include many more, including mavidin, peonidin, delphinidin, cyanidin, petunidin, and pelargonidin. Raspberry only contains cyanidin. Plum contains cyanidin and peonidin. Radish contains pelargonidin. Clearly these compounds have great power for sorting out the presence or absence of the various red fruit and vegetable products used in food. These markers have been used to detect deception in many red products.

Another example is D-malic acid, which is not synthesized by plants. Plants normally produce only L-malic acid. D-malic acid can be assayed by chiral chromatography or with an enzymatic method. The enzymatic approach is based on D-malate dehydrogenase, an enzyme that oxidizes D-malic acid to pyruvate and carbon dioxide in the presence of an appropriate cofactor. For the chromatographic procedure, samples have been analyzed on a polystyrene divinylbenzene copolymer column with 16-mM L-valine/8-mM copper(II) acetate adjusted to pH 5.5 with NaOH as mobile phase and detection at 330 nm. This method was suitable for determining the adulteration of apple juice with D, L-malic acid.

The theme of enantiomeric purity of organic acids has also been applied to grape juice. Grape juices with added synthetic malic and tartaric acids were subjected to ultrafiltration after decolorization with charcoal and separated by HPLC on a TSK gel QAE-25SW anion-exchange column. Polarized photometric detection (PPD) at 520 nm and UV (ultraviolet) detection at 333 nm were used. UV detection gave positive peaks for each acid but PPD detection gave a positive peak for each L-isomer, a negative peak for the D-isomer and no peak for the racemate. The coupled PPD/UV detection system did not require the physical separation of L- and D-isomers. The method is suitable for the routine examination of grape juice adulteration at the 5% level.

The strategy of a single marker is very cost effective if the suspected adulterant is known. However, if the adulterant is not present, little information has been obtained towards authenticating the unknown. There are still many other possible adulterants that need to be eliminated and a practitioner may wish to consider another strategy even though it might add to his or her costs.

4.2 Deviation in a Component

Sometimes unique markers that indicate the presence of an adulterant are unknown or nonexistent. In these cases another strategy or theme is necessary. Adulterants often change the ratio or ranges of common components. In these cases, an observed value outside of the normal range can provide the necessary evidence.

Statistical analysis is more complex than just achieving a confirmed detection. The mean and distribution of a control population are compared to the value associated with the unknown. A likelihood that the unknown is a member of the population is easily calculated by using a normal approximation which is usually adequate but the specific distribution should be examined before selecting a cutoff point. Two standard deviations above or below the mean is a typical choice. Ultimately, a practitioner needs to decide whether to accept or reject a sample. Statistical analysis provides a rationale for the decision. Multiple questionable samples from a single source can be used to increase the sensitivity of this approach. Five samples each with a likelihood of being real of less than 5% is an unlikely event and would certainly provide a reason to investigate further.

Proline and sorbitol levels in apple juice are examples of these types of indices. On a single strength basis, proline is generally 2–5 ppm in apple juice. When it is greater than 10 ppm, it becomes likely that pear juice was added. Clearly, the more proline the greater the suspicion. Sorbitol can provide similar information. In apple juice, sorbitol levels are typically 0–1%. Sorbitol values much greater than 1% again indicate the probable presence of pear juice. SIRA with $^{13}$C also shows deviation. Authentic apple juice will generally yield a value of −26 to −24 parts per thousand. Anything greater than −22 parts per thousand indicates that corn or cane sugars have been added.
In both of these examples, the experts argue about the exact values that should be accepted or rejected. Ultimately, the discussion revolves around the authenticity of various unusual samples that affect the distribution and range of the authentic population. The only way to resolve these differences is to accumulate large databases of samples where authenticity is not questioned.

One recurring approach that is used to overcome the database limitation is to employ an internal reference. For example, in pineapple juice or partially reconstituted pineapple concentrate the $^{13}$C levels in the sugars were compared with those in the organic acids when these components were separated on a simple cation-exchange resin, AG50W-X8\(^8\), which removes amino acids and other cationic substances (retained on column), an anionexchange column, AG1-X8 which retains organic acids and other anionic substances, while sugars were removed by washing with water.\(^{16}\) The sugars, and malic and citric acids were analyzed and the $^{13}$C isotope ratios were determined using MS (mass spectrometry) coupled to an elemental analyzer. This procedure is appropriate for pineapple because one of the major economic challenges has been in obtaining enough acidity in product from Thailand which has been the low-cost source since the late-1970s.

A second example is the use of honey protein to look for adulteration.\(^{17}\) Protein was isolated from honey by tungstic acid precipitation, and the $\delta^{13}$C value of the protein and the honey was determined by the AOAC Official Method 31.158-31.161. A difference of more than 1.0% suggests adulteration of the honey. This theme was also followed, using malic acid as a control in apple juice.\(^{18}\)

This internal control approach is used for data besides stable isotope ratios. Practitioners examine fructose : glucose ratios, ratios of various flavonoids, and D-malic acid as a fraction of total malic acid. Nevertheless, this approach is still limited to confirming the presence or absence of a specific adulterant or family of adulterants. In contrast to the specific marker approach, these procedures do confirm that at least one attribute of the sample is within the normal range, but there is still much room for adulterants to go undetected.

### 4.3 Matrix of Specific Components

The matrix approach promoted by Brause et al.\(^{19}\) is the approach taken by most practitioners for authenticating juices. It can be applied to other matrices as well. In this approach an array of tests is performed that are designed to detect the full array of expected adulterants. Such an array usually generates enough data for most unknown adulterants to yield one or more suspicious values. This is not always true. Apple juice concentrate adulterated with hydrolyzed inulin is an example of an adulterant missed by people who were slow to adopt the capillary chromatography procedure.\(^{20}\)

Two practical matrices are presented in Table 1 and in Table 2. Table 1 presents the matrix for apple juice. It provides a rationale for detecting pear juice, beet sucrose, beet invert sugar, high-fructose corn syrup (HFCS), cane invert sugar, cane sucrose, hydrolyzed inulin, and totally synthetic ingredients such as those sold in the infant apple juice scandal in 1988. Similarly, Table 2 presents a matrix for orange juice. In orange juice, the likely adulterants are somewhat different. Grapefruit juice and pulp wash need to be considered. Matrices such as these can be run for about $500 per sample at a contract laboratory which will provide an interpretation. However, different contract laboratories will have their own versions of these matrices. Some will add methods. Some will use different values. There is still some art in the authentication process.

This approach still has the potential to miss an adulterant. Fundamentally, this approach is looking for a specific set of adulterants and has the potential to miss an adulterant selected to avoid detection by this screening procedure. However, this is more complicated than it sounds. A successful adulterant must have much of the general composition of the food product in question to avoid detection and still be cheap enough to justify the effort and risk. This concern prompts some professionals to hold back some information about their matrix to leave some uncertainty for the would-be adulterators.

### 4.4 Pattern or Profile Recognition

This strategy or approach is the new frontier in authentication and is still evolving. Instead of using a shortlist of analyses like the matrix approach, one or more profiling methods are used. A profiling method is characterized as one that generates large amounts of information that can characterize a product. Often much of this information is not understood directly, but is instead just considered descriptively. This is not unlike the whirls and patterns in a fingerprint.

Chromatographic and spectroscopic methods have great potential. The key is in developing specific procedures that yield a profile that includes the information necessary to distinguish authentic from adulterated samples. One of the major challenges in this area is the lack of a standard data format or a standard procedure for generating the profiles.

Near-infrared (NIR) spectroscopy falls into this strategy. It has been applied to a wide range of foods and ingredients.\(^{21}\) Usually, the spectra look so similar that chemometric analysis tools are required to extract the information and make possible discrimination between authentic and adulterated samples. Many practitioners...

are uncomfortable with such approaches because it is difficult to check what the statistics indicate manually.

GC yields complex chromatograms that can be used to authenticate products. In one example, 56 pure butter samples from six countries were analyzed.\(^{(22)}\) Model adulterants included soya oil, maize oil and lard. Samples were injected onto a 3% OV-1\(^{\text{TM}}\) packed column with He as carrier gas. The results were evaluated by partial least squares (PLS) regression and neural networks. The results from the two procedures were compared. Whereas neural networks were only used for classification of the samples, PLS also generated quantitative results and was able to extract significant patterns in small calibration sets.

The analysis of vanilla flavors and extracts is a challenging area of authentication. Vanillin, the most important flavor component, is readily synthesized and consumers will pay a premium for natural product. Efforts continue to apply site-specific natural isotopic fractionation study by NMR (nuclear magnetic resonance) to this problem.\(^{(23)}\) Analytical improvements have been made but further progress is desired. The key compounds involved are vanillin and \(p\)-hydroxybenzaldehyde.

An alternative approach is also being developed using a technique described as Global Fingerprint Verification\(^{\text{TM}}\). The partial results of an unpublished trial conducted with the Flavor Extract Manufacturers’ Association (FEMA) are shown in Figure 1 (see Table 3). It is readily apparent from the false color image that Veritek Verification Technologies, Inc. have a technology that shows great promise as a pattern recognition system for categorizing food products. In this illustration, many of the various types of vanilla are correctly categorized with a single dye. In practice many orthogonal dyes would be used to generate a profile that is very specific and sensitive to a wide range of changes. Statistical analysis of the data showed complete discrimination. The automated system routinely performs comparisons in four replicates with only a negligible increase in costs. This technology has already found great success in pharmaceuticals and some success in the food industry.

Other profiles are mentioned in the product sections of section 6. These techniques all share the characteristic of collecting large amounts of data and collecting information about the whole product, not just one or two components. This distinction has the potential to break the cycle of adding a new method every time there is a new breakthrough in adulterating products. There will be a learning curve for both the practitioners and those who make decisions based on the advice of the practitioners.

5 ECONOMICS OF TESTING

The economics of testing are complicated. Testing is expensive. No food processor wants to incur the cost. Most food processors believe that they deal with reputable suppliers and therefore have little reason to test. Regulators must respond to political pressure. In the United States this means that they are intent upon pursuing food safety issues. Regulators do not have time and resources to chase an economic adulteration. Consumers want the product to be inexpensive, healthy
and taste wonderful. At the bottom line, no one wants to test. It is amazing that the marketplace is as fair as it is.

For regulators, academic and trade association scientists, there is very little choice. If they receive money to monitor the market, they need to follow through. Granted that such players have liberty in seeking funding, but in practice their decisions about what and how much to test are determined by external factors. The situation for a food processor is somewhat different.

An intentional adulteration by a food processor is not an interesting case for self-monitoring. It is a willful fraud. Someone has made a conscious decision to try to sell inappropriate product. Any testing done by such a processor will be to test the quality of the deception and will be very limited. Such a fraud will decrease the cost of goods and should translate into a lower price, a higher profit margin, or a larger marketing budget. The harsh reality of this unfair competition should prompt competitors to watch each other’s products. This type of surveillance should guarantee that adulteration will eventually be discovered.

Unfortunately, if a flexibly minded adulterator is not too greedy, he or she is virtually impossible to detect. Every method and approach has a limit of detection. If a product consistently hugs the boundaries of authentic material, it is likely that the product has been modified. A more intensive investigation is warranted. It is possible that a geographic or varietal variation is responsible but this has not always been the case. Adulteration is increasingly sophisticated and in a low margin business, even a little help can greatly increase profitability.

If processors do not want to monitor their competitors and deal with the problems in their marketplace, they need to insure that regulators or other third party players such as a trade association have the resources to monitor the marketplace. However, the processor must bear in mind that this is a two-edged proposition. They need to be confident that their own products will not be found suspect. There are many examples where this has occurred for specific commodities. Generally this approach works for commodities that are largely vertical, i.e. where there is little risk of buying adulterated ingredients. The goal is to insure that market participants do not intentionally adulterate their products.

For the case of unintentional adulteration, the situation is more interesting for a food processor. If a food processor unknowingly purchases an adulterated ingredient, the product made will be adulterated even though there will have been no intent. The food processor must grapple with the following questions to determine how best to protect the business:

- How likely is the purchase of an adulterated ingredient?
- How likely is any unintentional adulteration to be detected?
- What is the cost of a detected adulteration event?
- How effective is a testing program in preventing unintentional adulteration?

With answers to these questions, a food processor can estimate the extent of exposure and consider how to proceed. Unfortunately, answers to these questions are not exact. If an ingredient is in short supply and expensive, the risk of purchasing an adulterated lot is probably higher than if the ingredient is abundant and cheap. If the supplier is a long-term business partner that you have learned to trust, the likelihood of a problem decreases. However, that trust should be based on facts and not on a friendly smile. Once time purchases are the most likely to cause problems, especially when the entire history of the lot is not known.

The impact of a major unintentional adulteration scandal to a food processor is generally substantial but need not destroy the franchise. The food processor generally needs to recall the affected product, which is an expensive process. In addition the processor needs to act to regain the public trust by explaining how this bad thing happened and why it will not happen again. For a food processor, the potential loss in consumer confidence is probably the most damaging aspect of this turn of events.

It takes a good and extensive testing program to seriously reduce the risk of purchasing adulterated ingredients. However, when a sound testing program is coupled with an approved supplier list and long-standing business relationships are built up, the risk can be greatly reduced at a much lower lost.

Testing and authentication monitoring are like a safety program. It is difficult to eliminate all accidents but the money spent on safety is usually wisely spent if the safety program is well designed and well implemented. A testing and authentication program needs to be an integrated part of the business. It is a tool for purchasing. It is a tool for marketing and sales. However, a poorly designed program is just a way to spend money and may yield no benefits. No company seems immune unless it is entirely vertical. The challenge is to place a value on the various costs, benefits and potential risks and seek an optimal solution.

6 SPECIFIC METHODS BY PRODUCTS

Although it is impossible to cover all commodities where adulteration is a potential problem, owing to space limitations here, the following overviews should provide some access to the literature. The intent is
to illustrate themes used in detecting adulteration. Ashurst and Denis provide a good overview of many methods, including stable isotope analysis, NMR, infrared (IR) spectroscopy, oligosaccharide analysis, enzymatic analyses, DNA and PCR (polymerase chain reaction), electrophoretic, antibody, and various statistical methods for using this data. The intent in the following subsections is to provide numerous recent examples.

### 6.1 Apple Juice

Apple juice has been used as an example throughout this article. It is well characterized and has been involved in several adulteration scandals. The authentication matrix presented in Table 1 includes seven possible adulterants. However, it does seem appropriate to include a few more references and procedures.

A capillary GC method for the detection of fingerprint oligosaccharides, resulting from the adulteration of fruit juices and other foods with commercial sweeteners, has significantly changed the practice of authentication. After lyophilization and derivatization with TriSil Z™, the food samples were analyzed on an HP-5™ column. The limit of detection for several different sweeteners is about 5%. At this point, no practitioner of authentication should be unaware of this method.

Given the importance of racemic malic acid in the detection of apple juice adulteration, one more method does not seem out of place. L-Malic acid is the predominant acid in apple juice and no D-malic acid should be present; the presence of D-malic acid indicates adulteration of the juice with synthetic malic acid, the racemic mixture that contains 50% D-malic acid. Apple juice samples were extracted with a C18 cartridge, filtered and chromatographed on two reversed-phase LC (liquid chromatography) columns connected in series, with 0.2 M phosphate buffer as mobile phase and detection at 214 nm to determine the total malic acid. L-malic acid was determined with the use of an enzymic test kit (Boehringer–Mannheim, Indianapolis, IN, USA), with dilution of the sample by a factor of 10 and absorbance readings at 365 nm as modifications.

It is important to recognize that not everything that is tried works. Sometimes a data set will contain enough information to make all of the desired discriminations. In this example, a pattern recognition program was used in conjunction with a spreadsheet program for classification of authentic apple juice samples of different varieties and geographical origins. The data analysis included HPLC determination of sugars and organic acids, determination of titratable acidity, measurement of degrees Brix, enzymatic determination of L-malic acid and determination of stable carbon isotope ratio. The method successfully classified samples but was not sensitive enough for authentication purposes. In most instances, adulterants were detected at concentrations over 20%.

And last, before leaving apple juice, it seems appropriate to illustrate that an alternative procedure can accomplish the same ends. Research has identified other markers to detect the presence of pear in apple or apple in pear. In this procedure, fruit was extracted with methanol, evaporated and resuspended in water before a column cleanup procedure. Juices could be applied directly to the cleanup column. Various fractions were eluted from this column and analyzed on a column of ODS (octadecylsilane)-Hypersil™. Isorhamnetin glucoside (limit of detection 10 ng), which was undetectable in apples, is reported as an indicator of pear. Phloretin glucoside and phloretin xyloglucoside (limit of detection 7 ng) is reported as an indicator of apple in pear juice.

### 6.2 Botanicals

Although perhaps not typical food components, many botanicals are entering the diet in dietary supplements and increasingly are being added to mainstream foods. Where results have been published, the approaches for authentication are similar. For many of these materials, methods are marginal at best. However, some procedures have been published and others are under development. Authentication and potency are major issues. In many cases standards are difficult to obtain and there is much discussion about the active components.

For botanicals, the most common deception is the replacement of the desired material with another plant material with the same general appearance. It is not easy to distinguish between various finely ground plant materials. However, at this point it is often difficult to distinguish between low-potency botanicals and mislabeled product. This has prompted some work.

Researchers reported the evaluation of a commercial system, REMED HS, for screening Chinese herbal medicines for adulteration by neutral and basic Western medicines. The system involved online sample purification and extraction, separation by HPLC, scanning UV detection, and evaluation of the spectral and retention data by reference to a library consisting of data for 555 drugs and metabolites. The technique was applied to the analysis of five herbal medicines. Detection limits for most adulterants were 100–300 ng mL⁻¹.

For many botanicals, enantiomeric composition is a useful tool for detecting adulteration. In this example, essential oils were extracted from seeds of dill, and annual and biennial caraway with hexane, hydrodistillation or a combination of both methods. Analysis was by GC with a cyclodextrin in the stationary phase separating authentic samples of (+)- and (−)-limonene, (+)- and (−)-carvone,
and (−)-cis/trans-carveol. The enantiomeric composition of dill and annual and biennial caraway seeds were similar, except that dill had a higher (−)/total limonene ratio and contained no (−)-cis-carveol.

It is not surprising that regular capillary GC is useful in authenticating botanicals, given the high resolving power of the technique. In this particular example, solid-phase extraction was the preferred method of sample preparation for analyzing espomheira santa, an anti-ulcer drug, because it gave a cleaner sample and consumed less solvent. Resulting solutions were analyzed by GC on a column coated with OV-17-OH and FID (flame ionization detection). This method allows the detection of friedelane-3-ol and friedelin which can be used as markers for the authentic anti-ulcer drug.

In another GC example, supercritical extraction was selected as the method of choice for preparing the samples. Guava leaves were cut in pieces, mixed and ground with granulated celite, and extracted in a supercritical fluid extraction cell using CO2. The extracted material was trapped by passing the CO2 effluent through propan-2-ol. The extracted samples were analyzed by capillary GC on a DB1 column.

Materials such as saffron or black pepper are valuable and are thus more likely to be adulterated. Saffron has been characterized by microscopy and by color reactions (under the microscope) with phloroglucinol, H2SO4 and molybdophosphate. Saffron can also be differentiated from some substitutes because it is not fluorescent under UV radiation. TLC (thin-layer chromatography) of extracts in aqueous 80% ethanol is carried out on silica gel under UV radiation. TLC (thin-layer chromatography) of extracts in aqueous 80% ethanol is carried out on silica gel under UV radiation. The three main spots (retention factor 0.56) are caused by the principal pigments of saffron.

Papaya seeds have been used to adulterate black pepper. This form of adulteration can be detected by measuring benzyl glucosinolate (glucotropaeolin). Samples of papaya seed–black pepper are de-fatted by extraction with 2,2,4-trimethylpentane–propan-2-ol (9:1) and then air dried. The remaining sample is then extracted with boiling water, sinigrin is added as internal standard, and the solution is treated with barium and mercury acetates. After centrifuging, the supernatant liquid is cleaned up on a microcolumn of DEAE Sephadex A-25. The papaya marker is eluted with 20-mM pyridine acetate and determined by GC. There is also an enzyme procedure based on the release of glucose.

6.3 Coffee

Coffee is another valuable commodity. The economies of many central American nations are strongly tied to this commodity. The value of coffee is linked to its geographic origins and the variety. It should come as no surprise that methods for characterizing coffee and coffee solids have been developed.

NIR and mid-IR spectroscopy has been reported to be useful in authenticating varieties of coffee and in detecting adulteration. In one study, arabica and robusta coffee beans were ground and lyophilized. NIR spectra were recorded in reflectance mode at ambient temperature over 400–2498 nm at 2-nm intervals. Mid-IR spectra were obtained by FTIR (Fourier transform infrared) spectroscopy over 800–4000 cm−1 at 8 cm−1 resolution. Using discriminant analysis, varieties could be distinguished. In another study, most of the same researchers compare several data processing techniques using IR spectroscopy and chemometrics to detect added glucose, xylose and fructose, or added glucose, starch and chicory. An artificial neural net shows the greatest promise for extracting the classification information. Another related procedure shows promise for authentication. Extracts of arabica, robusta and their blends were either freeze dried or dried on glass fiber filter paper under reduced pressure, and NIR spectra of the dried material were recorded from 1100 to 2498 nm. The spectra were analyzed by principal-components and factorial discriminant analysis. Of 65 samples, three were misclassified when presented on filter paper, and nine were misclassified when presented freeze dried. Finally, using a different type of sample preparation, 28 samples of roasted coffee beans were ground and mixed with KBr. IR spectra were recorded at 800–4000 cm−1, with a resolution of 8 cm−1, with a diffuse reflectance accessory. Differences between the spectra from arabica and robusta were observed around ~1744 and ~1150 cm−1. Considerable grouping of the spectra, according to the species, occurred. Conventional discrimination analysis applied to the principal component scores was able to give 100% discrimination between the two species. The applicability of the method is limited by the small samples used but it should be useful for detecting adulteration in commercial coffee.

Coffee and coffee solids have been adulterated with various materials. Detection methods have focused on simple sugars, a recurring theme in authentication testing. For example, commercial soluble coffee can be adulterated with coffee husks or parchment. These adulterants can be detected by using xylose as a tracer. Xylose was determined in 700 commercial coffees using anion-exchange chromatography with PAD. The cutoff limit was a total xylose concentration of 0.4% above which the coffee was considered adulterated. Xylose concentration ranged from 0.01 to 3.15%. Of the samples analyzed, 81 were regarded as adulterated with xylose. Total glucose and free manitol were also examined as tracers for adulteration with coffee husks, or parchment.
and coffee husks, respectively. Free mannitol levels >0.30% were a sign of adulteration. Free mannitol ranged from 0.01 to 1.55% and total glucose ranged from 0.46 to 42.5%. Adulteration has also been detected using enzyme assays for these sugars or by using GC. All three approaches have found use in many other matrices.

The use of stable isotope techniques is another recurring theme. Stable isotope methods have been applied to coffees and coffee extracts by extracting the caffeine. Coffee beans were extracted with boiling water and the extracts were treated with lead carbonate or MgO and filtered. Caffeine was extracted with CHCl₃. Most of the solvent was evaporated and the caffeine was precipitated with light petroleum and crystallized from methanol. The ¹³C:¹²C and ¹⁵N:¹⁴N ratios of the crystals were determined by isotope ratio MS after combustion and the site-specific ²H:¹H ratios were determined by NMR after combustion and reduction of H₂O with Zn. Principal component and discriminant analysis permitted the differentiation of natural and synthetic caffeine and of American and African coffee.

### 6.4 Dairy Products

Dairy products are a valuable source of protein and calcium. Special dairy products have been developed in many cultures to take advantage of the taste and functional differences of milks from different species. These specialty products are again subject to adulteration from milk from other animals, usually bovine milk. In addition, milks are often adulterated with other fats that are less costly than milk fat. Whey and whey proteins have found their way into some products and ingredients as well. There is also the problem of dilution with water. For these commodities, again, the same methodologies and approaches have been applied.

Capillary GC has been used to examine the triglyceride profiles of Mexican cheeses. Cheese was ground for 5 min and extracted with hexane and injected onto a fused-silica column coated with SPB-50. Although the proportions of triglycerides in different cheeses determined on SPB-50 were similar, the concentrations of individual triglycerides and the total content of triglycerides varied between the cheeses. Adulteration of one sample with vegetable oil was detected. A similar procedure has been applied to detect refined animal and vegetable fat in milkfat.

The dodecanoic-to-decanoic acid ratio for detecting species adulteration has been selected but the process is the same, the key being to identify a protein that does not belong in the product. As an example, buttermilk powders, nonfat dry milk, total milk proteins, sodium caseinate, whey proteins and fat globule membrane (FGM) proteins were examined with SDS/PAGE (sodium dodecylsulfate/polyacrylamide gel electrophoresis). Protein bands were stained manually for 15 min in 0.1% Coomassie brilliant blue R dissolved in ethanol–acetic acid–H₂O (3 : 1 : 6). Band densities were quantified by scanning at 600 nm in a Bio-Rad video densitometer. The limit of detection for the FGM protein was 52%.

Researchers have reviewed other approaches that have been used to measure and profile triglycerides in milk to authenticate various products. Methodologies have included HPLC, IR spectroscopy, and isotopic analysis. Differential scanning calorimetry has also been considered for detecting animal fats in butter.

The detection of dilution with water is a very old problem for dairy products. The village pump added to the milk supply for many years. Various approaches can be used to detect water addition, including density, refractometry, and other intrinsic properties. Of these intrinsic properties, freezing point depression seems to have international acceptability. Alternatively, a purchaser can use IR and measure the protein, butterfat, and other milk solids as a basis for purchase. Water content is not particularly important under these conditions.

The problem of species adulteration continues to be the focus of research. Recently, pyrolysis MS was applied to the problem. In order to measure the adulteration of sheep’s and goat’s milk with cow’s milk, portions of the pure milks and binary mixtures were applied to Fe/Ni foils and dried at 50°C for 30 min. For pyrolysis MS, the foils were heated at 100°C for 5 s before Curie-point pyrolysis at 530°C for 3 s (temperature rise time 0.5 s). Data were collected over the range m/z 51–200 and normalized to the total ion count. Cluster analysis of the spectra of the pure milks showed that the major source of variation between the different milks was not the variable fat content. Chemometric models were able to predict concentrations of cow’s milk of ≤20% with errors of ≤±1.5% in samples on which they had not been trained.

Most researchers have focused on proteins to detect species adulteration. Different separation methods have been selected but the process is the same, the key being to identify a protein that does not belong in the product. As an example, buttermilk powders, nonfat dry milk, total milk proteins, sodium caseinate, whey proteins and fat globule membrane (FGM) proteins were examined with SDS/PAGE (sodium dodecylsulfate/polyacrylamide gel electrophoresis). Protein bands were stained manually for 15 min in 0.1% Coomassie brilliant blue R dissolved in ethanol–acetic acid–H₂O (3 : 1 : 6). Band densities were quantified by scanning at 600 nm in a Bio-Rad video densitometer. The limit of detection for the FGM protein was 47%.
band was 420 ng. Two unique FGM proteins were clearly visible in authentic buttermilk powders. SDS/PAGE using the automated system required for <3h. Other researchers have used capillary electrophoresis instead of SDS/PAGE. These procedures gave good separation of the serum proteins and caseins. Root square deviation (RSD) for migration times and peak areas were 0.085% and 2–4%, respectively. Electropherograms of goat, cow and sheep milk were compared and were sufficiently different to permit the detection of 1% adulteration from another species. The method could also detect the effect of heat damage on casein, and detect the addition of dried powdered milk to fresh milk. To detect cow’s milk in goat’s milk, a researcher showed the absence of αS1-casein in goat’s milk providing a sensitive and quantitative measure of the cow’s milk.

Speciation has also been effected by HPLC. The presence of 1–3% of cow’s milk in samples of sheep, goat’s, mare’s and human milk was detected by subjecting whey or casein samples to HPLC on a reversed-phase Nucleosil 300-5C5 column with aqueous 0.1% trifluoroacetic acid and an acetonitrile gradient. Detection of species-specific milk proteins was by absorbance at 280 nm or by fluorescence detection at 340 nm. For sheep and goat’s milk, the presence of >1% of cow’s milk was shown by a peak associated with bovine β-lactoglobulin A, which was detected at 290 nm in chromatograms of whey samples. The method was also applied to yogurt and cheese samples.

Whey protein is a special problem in dairy products. It has already been mentioned several times. It can often be detected in the protein profiles mentioned above. In addition, whey addition to nonfat dry milk powder can be detected by an elevation of the thiol to milk protein ratio. Whey proteins can also be detected by another compositional variance, determined by changes in the amino acid profile after hydrolysis.

6.5 Essential Oils

Essential oils are expensive and are extensively used in flavors and cosmetics. Many of these oils are well characterized and the compositions are known. Authentic or natural oils are more valuable than synthetic oils, given the importance of origin in labeling. This has prompted the development of many chromatographic procedures. Given that many of these oils contain enantiometrically pure constituents, enantioselective GC is useful in authenticity control for some economically important essential oils. German researchers report a HPLC approach for detecting ethyl p-dimethylaminobenzoate or menthol anthranilate in lemon oil by HPLC. Other researchers have used multidimensional GC coupled with MS and IR to characterize eucalyptus oil. A multidimensional chiral system was used to characterize rose oils. The method was applied to the chirality evaluation of cis/trans rose oxides, linalol and citronellol from both authentic Bulgarian and Turkish rose oils and commercially available oils. The enantiomeric ratios of genuine constituents of the oils are discussed as indicators of naturalness. Mentha oils have been examined for illegal adulteration using TLC and chiral GC. Other researchers report fingerprints and composition information for a variety of oils including cardamom, lemon grass, nutmeg, etc.

Using their high-field NMR, researchers developed a method for detecting adulterated bitter almond and cinnamon oils based on measuring the site-specific deuterium content of benzaldehyde, which is indicative of its source, viz. synthetic (ex-toluene and ex-benzaldehyde), natural (ex-kernels from apricots, peaches and cherries and ex-bitter almonds) and semisynthetic (ex-cinnamaldehyde extracted from cinnamon). Benzaldehyde is the main component of bitter almond oil and samples were analyzed directly. A purified cinnamaldehyde sample was isolated from cinnamon oil and transformed to benzaldehyde by refluxing with 3% aqueous K2CO3.

In an approach similar to that for benzaldehyde, adulteration of natural mustard oil with synthetic allyl isothiocyanate can be detected by site-specific deuterium NMR. The four monodeuterated isotopomers of allyl isothiocyanate were observed by 2H-NMR, and site-specific hydrogen isotope ratio determinations were performed. Different results were obtained for the natural and the synthetic compounds. The 13C, 15N and 34S isotopic deviations and other isotopic parameters were subjected to principal components analysis and the results indicated the geographical origin of natural mustard oils.

6.6 Maple Syrup and Honey

Maple syrup and honey are relatively unique. They are both mainly sugar but are valued highly for their taste. Maple syrup is mainly sucrose and has been adulterated variously with cane sugar, beet sugar, and other sweeteners. Honey is a mixture of fructose, glucose and a little sucrose. Products differ somewhat geographically but are often valued above and beyond these differences. Honey is often identified having been made from a particular blossom which does impart character to the honey. Given the high sugar content of these two commodities, it is relatively difficult to detect sugar addition if the right materials are used and are used at moderate levels.

It should come as no surprise that isotopic procedures have been dominant. Stable isotope techniques are useful for examining the origins of sugars. Maple syrup can be analyzed by deuterium site-specific nuclear isotope
fractionation NMR after the conversion of sugar to alcohol. Overall 13C:12C isotope ratios can be determined by SIRA/MS. With this data, added sugar could be determined at levels of 5–20% of total solids. The δ13C values for maple syrup, cane sugar, and corn syrup are ~24.12, ~11.29 and ~11.85 parts per thousand, respectively. Similarly, 13C:12C isotope ratio can be used to test honey for the presence of corn or maize syrup.

An alternative to the isotopic approaches for detecting added sugars is oligosaccharide analysis, which can be performed in a number of ways. In one example, maple syrups were diluted with HFCS or beet medium invert sugar (BMIS). Samples were prepared by ion exchange through a column comprising AG50W-X8™ cation-exchange resin and a column of AG1-X8 anion-exchange resin followed by a C18 Sep-Pak™ cartridge and a filter. Samples were analyzed by HPLC on a CarboPac PA1™ column equipped with sodium acetate with a gradient of sodium hydroxide. PAD was used. Fingerprint oligosaccharides were shown to be present in the inexpensive sweeteners (HFCS and BMIS) which were not present in pure maple syrup. The detection limit was 5% for adulteration of maple syrup with these inexpensive sweeteners. In another paper, researchers used a sample cleanup step to concentrate oligosaccharides from honey and other syrups prior to HPLC analysis. Honey or syrup was diluted with water, and the higher saccharides (which are absent from authentic honey) were concentrated by medium-pressure LC on carbon–Celite with aqueous 7% ethanol as wash solution and aqueous 50% ethanol as mobile phase. The eluted sugars were determined at levels of 5–20% of total solids.

Returning to another common theme, capillary GC has been used to examine the oligosaccharides of honey for authentication. Honey and sweetener samples were diluted with H2O to a Brix value of 5.5. Samples (250 μL) were lyophilized at 25°C for 10 h and derivatized with 0.5-mL Tri-Sil Z by heating to 80°C for 1 h. The TMS (trimethylsilyl) derivatives were analyzed on a column coated with DB-5 and FID. The method was used to determine the adulteration of honey with invert syrups (beet or cane). The detection limit for invert sugar addition was 5%.

Flavanoids from honey have been considered as a tool for characterizing types of honey. Honey (~50 g) was mixed with 5 parts of H2O (acidified to pH 2 to 3 with HCl) until completely fluid, and then filtered through cotton. The filtrate was passed through a column of Amberlite™ XAD-2, which was then washed with acid H2O, followed by neutral H2O (pH 7), before elution of the phenolic fraction with methanol. The eluate was concentrated under reduced pressure, dissolved in methanol and further purified by passage through a column of Sephadex LH-20. The second fraction, containing the flavonoids, was concentrated, redissolved in methanol, and analyzed by HPLC on a LiChrocart™ RP-18 column. Sixteen flavonoids were identified. Later work characterized the flavonoids found in Portuguese heather honey.

6.7 Meat Products

Meat is another important class of commodity. As economic status rises, meat consumption rises. However, not all meat is valued equally and there are ways that meat has been extended, including the use of vegetable protein and the proteins from other species. Different species have been mixed, diluting an expensive commodity with a less expensive commodity. The analytical problems concerned with meats are complicated by the extreme changes that occur during processing and cooking. Nevertheless, there are a wide variety of procedures that have been developed.

The most common approach to detecting other species is with an antibody in an immuno-assay of some type. For example, tropinin antigen was prepared and antisera were raised in rabbits. The antisera were used in an agar gel immunodiffusion test to identify the species of fresh, cooked and decomposed cattle and buffalo meat. Rabbit anticattle tropinin serum was species specific and showed no cross-reactivity. It could detect up to 10% adulteration of fresh cattle meat with other meat and decomposed meat. Rabbit antibuffalo tropinin serum had to be adsorbed on glutaraldehyde to make it species specific. It could detect as little as 1% adulteration in fresh buffalo meat and decomposed meat. Neither sera could detect cooked meats.

Other researchers used lactate dehydrogenase (LDH) to detect turkey adulteration in beef or pork. The sample was homogenized with 0.15-M NaCl in 0.01-M sodium phosphate buffer at pH 7.2 and centrifuged. The supernatant was filtered and diluted 1 : 100 to 1 : 10000 in 0.1-M sodium phosphate buffer at pH 7.2 containing 0.15-M NaCl, 1% BSA (bovine serum albumin) and 0.2% Tween 20. Portions were incubated for 1 h at 37°C in microtiter plate wells that had been coated with LDH D5E mAb. After washing, biotinylated LDH B3C mAb was added for 1 h at 37°C and washed again. Finally, an incubation with avidin–horseradish

PAD was used. Fingerprint oligosaccharides were shown to be present in the inexpensive sweeteners (HFCS and BMIS) which were not present in pure maple syrup. The detection limit was 5% for adulteration of maple syrup with these inexpensive sweeteners. In another paper, researchers used a sample cleanup step to concentrate oligosaccharides from honey and other syrups prior to HPLC analysis. Honey or syrup was diluted with water, and the higher saccharides (which are absent from authentic honey) were concentrated by medium-pressure LC on carbon–Celite with aqueous 7% ethanol as wash solution and aqueous 50% ethanol as mobile phase. The eluted sugars were determined at levels of 5–20% of total solids.

Returning to another common theme, capillary GC has been used to examine the oligosaccharides of honey for authentication. Honey and sweetener samples were diluted with H2O to a Brix value of 5.5. Samples (250 μL) were lyophilized at 25°C for 10 h and derivatized with 0.5-mL Tri-Sil Z by heating to 80°C for 1 h. The TMS (trimethylsilyl) derivatives were analyzed on a column coated with DB-5 and FID. The method was used to determine the adulteration of honey with invert syrups (beet or cane). The detection limit for invert sugar addition was 5%.

Honey (~50 g) was mixed with 5 parts of H2O (acidified to pH 2 to 3 with HCl) until completely fluid, and then filtered through cotton. The filtrate was passed through a column of Amberlite™ XAD-2, which was then washed with acid H2O, followed by neutral H2O (pH 7), before elution of the phenolic fraction with methanol. The eluate was concentrated under reduced pressure, dissolved in methanol and further purified by passage through a column of Sephadex LH-20. The second fraction, containing the flavonoids, was concentrated, redissolved in methanol, and analyzed by HPLC on a LiChrocart™ RP-18 column. Sixteen flavonoids were identified. Later work characterized the flavonoids found in Portuguese heather honey.

6.7 Meat Products

Meat is another important class of commodity. As economic status rises, meat consumption rises. However, not all meat is valued equally and there are ways that meat has been extended, including the use of vegetable protein and the proteins from other species. Different species have been mixed, diluting an expensive commodity with a less expensive commodity. The analytical problems concerned with meats are complicated by the extreme changes that occur during processing and cooking. Nevertheless, there are a wide variety of procedures that have been developed.

The most common approach to detecting other species is with an antibody in an immuno-assay of some type. For example, tropinin antigen was prepared and antisera were raised in rabbits. The antisera were used in an agar gel immunodiffusion test to identify the species of fresh, cooked and decomposed cattle and buffalo meat. Rabbit anticattle tropinin serum was species specific and showed no cross-reactivity. It could detect up to 10% adulteration of fresh cattle meat with other meat and decomposed meat. Rabbit antibuffalo tropinin serum had to be adsorbed on glutaraldehyde to make it species specific. It could detect as little as 1% adulteration in fresh buffalo meat and decomposed meat. Neither sera could detect cooked meats.

Other researchers used lactate dehydrogenase (LDH) to detect turkey adulteration in beef or pork. The sample was homogenized with 0.15-M NaCl in 0.01-M sodium phosphate buffer at pH 7.2 and centrifuged. The supernatant was filtered and diluted 1 : 100 to 1 : 10000 in 0.1-M sodium phosphate buffer at pH 7.2 containing 0.15-M NaCl, 1% BSA (bovine serum albumin) and 0.2% Tween 20. Portions were incubated for 1 h at 37°C in microtiter plate wells that had been coated with LDH D5E mAb. After washing, biotinylated LDH B3C mAb was added for 1 h at 37°C and washed again. Finally, an incubation with avidin–horseradish
peroxidase conjugate was accomplished in 30 min at 37 °C. Peroxidase activity was measured using 2,2'-azino-bis-(3-ethylbenzothiazoline)-6-sulfonic acid and H₂O₂ with detection at 405 nm. Linear relationships between the turkey LDH concentration and turkey content in beef and pork were found. The method detected 1% adulteration of beef or pork. Other researchers have reported enzyme-linked immunosorbent assays for distinguishing many different types of meat including unprocessed beef, sheep, horse, kangaroo, pig, camel, buffalo, and goat. None of these assays claim to work for cooked meat.

Alternatively, researchers have used protein profiles by electrophoresis or HPLC to detect adulteration. For example, scampi flesh was homogenized in aqueous 2% SDS (sodium dodecyl sulfate) and heated at 60 °C for 30 min. After centrifugation, the SDS extracts were separated by SDS/PAGE at 30 mA on 12% total acrylamide gels (2.67% crosslinker) with 4% stacking gels (2.67% crosslinker) and the gels were Ag stained. SDS/PAGE gave profiles characteristic of the shellfish species, enabling adulteration of *Nephrops norvegicus* with Pacific scampi or tropical shrimp to be detected in either raw or cooked meat. In a similar system, the identity of cooked meats was determined by extracting samples with 1% SDS containing 1 mM dithiothreitol and 10 mM EDTA (ethylenediaminetetraacetic acid). The samples were clarified by centrifugation, filtered and subjected to SDS/PAGE. After electrophoresis, proteins were fixed with methanol and acetic acid and stained with Coomassie blue. The meats from mammals and birds of different species produce characteristic patterns of bands, and adulteration by even 10% of meat from a different species could be detected with certainty in binary mixtures. In a third denaturing electrophoretic system, researchers measured duck and goose liver in foie gras.

HPLC has also been used to detect adulteration in chicken or turkey. Samples were blended with water and filtered before analysis on a Hi-Pore™ RP-304 in aqueous 0.1% trifluoroacetic acid. Elution was accomplished with a gradient from 37% to 60% acetonitrile–water (950:50). The peaks specific to the meat components were identified and quantified. The response was rectilinear from 5 to 100% of either chicken or turkey. The method gave reproducible results and other meats did not interfere.

Although protein profiles and immunoresponse have been more common, other approaches have been used. The adulteration of beef products by ≥5% of pork can be detected by determination of eicosadienoic acid (C₂₀:₂), which is present in pork at ≤0.7%, but in beef at 0.05%. The proportions of other fatty acids can be measured for the same purpose. Analysis was effected on a column coated with DB-Wax.

Before leaving meat, there is one more problem that merits examination. Feral or range animals often command a premium price. Canthaxanthin, a carotenoid, is present in farmed salmon or rainbow trout. Astaxanthin is present in wild fish. Either can be extracted from skin or muscle tissue into acetone and ethyl ether. The concentrated extract can be fractionated on Silica gel 60 by TLC with *r*-butyl alcohol–light petroleum (boiling range 40–60°C) (1:7) as mobile phase. All operations were carried out in dim light and with minimum exposure to air. Retention factors were 0.14, 0.43, 0.51 and 0.91 for astaxanthin, astaxanthin monoacyl ester, canthaxanthin diacyl ester and astaxanthin diacyl ester, respectively.

### 6.8 Olive Oil

Olive oil has been traded for millennia. Its value is determined by both origin and quality. The olive oil marketplace has been rocked by various scandals. Consequently, researchers have developed a number of strategies for authenticating this commodity. Common adulterations include adding other types of oil or manipulating the oil to improve the grade. Extra virgin olive oil is considered the most desirable.

As an example of a profiling approach, a combination of FT (Fourier transform)–Raman spectroscopy and multivariate analysis procedures was proposed for detecting vegetable oils (soybean, corn and raw olive residue oils) in virgin olive oil. The Raman spectra were recorded for 3250–100 cm⁻¹. The spectral data were processed using multivariate procedures. Six genuine virgin oil samples with different chemical compositions were selected to prepare the calibration standards containing 1–10% trilinolein. The method was tested with olive oil samples containing 1, 5 or 10% vegetable oil. Data analysis by regression on principal components produced the correct discrimination between genuine and adulterated oils for all the test samples and identified the correct level of contamination for 93% of the test samples.

Similarly, using NIR spectroscopy (over the range 400–2500 nm), extra virgin olive oil adulterated with sunflower, rapeseed or soya-bean oil could be detected. Using smoothed data over a 10-nm interval in the range 1100–2498 nm, and a combined first derivative, PLS and principal component analysis method, a 10-term equation was developed to predict the extent of oil adulteration. Other IR approaches have also been successful.

Other tools, including NMR, HPLC, GC and pyrolysis MS, have been used to detect adulteration. The same approaches are observed in most important food commodities. For example, the NMR spectra were recorded at 600.13 MHz. Multivariate analysis, including a principal components analysis and a variables selection method, was used to differentiate between the oils. Cluster analysis was used to reveal any natural groupings of the oils.
Diacylglycerols, linolenic acid, water, acetic acids, phenols and sterols could all be detected, so the method may be useful for authentication and quality control of virgin olive oil.\(^{(44)}\)

By HPLC, various groups examined different markers. For example, when olive oil was diluted with THF (tetrahydrofuran) and with methanol, it could be analyzed by HPLC on a Spherisorb ODS column with 0.05-M sodium perchlorate–methanol (1:9) and amperometric detection to measure tocopherols and tocotrienols as markers of authenticity.\(^{(95)}\) This reversed-phase HPLC method did not require saponification before analysis. Alternatively, an authenticity factor was developed for detecting linolenic-rich oils in olive oil by HPLC.\(^{(96)}\) Researchers have examined the triglycerides of olive oil by HPLC as a means of authentication.\(^{(97–99)}\)

Mass spectroscopy has also been applied to olive oil. Not surprisingly it can be quite effective in detecting corn oil and, in some approaches, other seed oils. The combination of pyrolysis MS with a neural network correctly assessed the authenticity of the olive oil samples.\(^{(100)}\) In another study,\(^{(101)}\) the \(^{13}\)C:\(^{12}\)C ratio was determined in individual fatty acids by GC combustion/isotope mass spectroscopy. Maize, rapeseed or groundnut oil were saponified with NaOH, cooled, acidified to pH 3 with HCl and the free fatty acids extracted with hexane. Hexane was removed from the samples under N\(_2\) and a 14\% BF\(_3\)/methanol complex was added and heated to form the methyl esters. The esters were dissolved in hexane and separated by GC on an SGE BPX-70 column. The column was interfaced with an isotope ratio mass spectrometer via a combustion interface that consisted of a ceramic furnace, packed with CuO/Pt catalyst, at 850°C. Consistent differences were detected in the \(^{13}\)C values of oils from different geographical regions. Not surprisingly, direct study of triglycerides and fatty acid profiles by GC can be used to authenticate olive oil.\(^{(102)}\)

### 6.9 Orange Juice

Orange juice is another commodity whose market has been scandalized by adulteration. The number of legal and legitimate products made that are designed to look and taste like orange juice is considerable. Some of these products contain little or no juice. Some use citrus extracts for flavor and others do not. Premiums are paid based on geographical origin. There are many methods for detecting various types of adulteration in orange juice, including C, H or O isotope ratio analysis; site-specific natural isotope fractionation with NMR; HPLC; tracer studies; the Petrus method involving UV and visible spectrophotometry; ICP/AES (inductively coupled plasma/atomic emission spectroscopy); and electrochemical detection.\(^{(103)}\) Researchers have supplied various statistical and pattern recognition tools. A matrix for this commodity has already been presented. However, this commodity is at the cutting edge in terms of new methods for authentication and in adulteration.

As we have seen for several other commodities, pyrolysis MS is being applied to authentication problems. Researchers have done the same for orange juice.\(^{(104)}\) Orange juice was centrifuged. The supernatant was applied to an Fe–Ni foil and dried for 30 min at 50°C. The sample was analyzed by pyrolysis MS. Data were normalized as a percentage of the total ion count in order to correct for the effects of sample size. Artificial neural networks, radial basis functions and PLS linear regression were evaluated as techniques for spectral deconvolution. Each method yielded excellent predictions for the level of sucrose adulteration, with a limit of detection of 1 g L\(^{-1}\) of added sucrose. However, PLS regression using eight latent variables for predictions yielded the best results. Furthermore, the inputs to multilayer perceptrons could be reduced by the use of principal components analysis from 150 masses to 8 principal component scores without any loss in the predictive ability of the model.

HPLC is an important tool for authenticating orange juice and most liquid food products. In the matrix presented above, it can be used to generate sugar profiles, measure the various organic acids and determine the flavonoids. Other more specific methods have also been developed for various authentication purposes. Specific examples include a study to measure the various saponified orange juice carotenoids.\(^{(105)}\) Carotenoids were isolated from orange juice concentrate by precipitation with Carrez reagent [zinc cyanoferrate(II)] and were recovered in a small volume of acetone. After extraction into petroleum ether and a solvent change to diethyl ether, the saponification was carried out with 6 mL of 10\% methanolic KOH in the dark. The ether layer was washed with water until free of alkali and evaporated to dryness. The residue was dissolved and analyzed by HPLC with diode-array detection on a nonendcapped C\(_{30}\) reversed-phase column in methanol–water–methyl tertiary butylether as mobile phase (18:1:1) and gradient elution to 19:0:1 in 12 min, and then to 43:0:7 in 20 min, to 3:0:1 in 30 min and 1:0:1 in 50 min. Thirty-nine carotenoid pigments were separated and identified. The six largest carotenoid peaks (at 430 nm) were identified as auroxanthin A, mutatoxanthin A, mutatoxanthin B, lutein, zeaxanthin and isolutein.

Using PAD, researchers have detected beet sugar adulteration of orange juice.\(^{(106,107)}\) Orange juice or BMIS were analyzed by LC on two columns of Carbo Pac PA1™ connected in series, with gradient elution with NaOH and sodium acetate with PAD. Results indicated the presence of several oligosaccharides in BMIS that were either in low concentration or nonexistent in orange juice;
The determination of these carbohydrates allowed detection of as little as 5% of BMIS as an adulterant sugar in orange juice. A switching valve was suggested to enable simple sugars to go to waste after the first column and so prevent overloading of the column and detector for processing large numbers of samples. This modification reduces the analytical time by 50% without any sacrifice in information or detection limits.

Grapefruit juice has found its way into orange juice at low levels. It is generally much cheaper. For detecting grapefruit juice addition to orange juice, HPLC analysis of naringin is suggested. Hesperidin is suggested to detect orange juice in grapefruit. For analysis, unfiltered juice was cleaned up on a polyamide column; elution was effected with methanol. The solution was evaporated to dryness, and the residue was taken up in 70% methanol or HPLC on a Hypersil™ ODS. Elution was carried out, either isocratically or with a gradient of methanol or acetonitrile in 1% acetic acid.

Pulp wash is another common adulterant of orange juice. Two approaches are reported for detecting it. The first is a little-used HPLC procedure where methoxylated flavonoids are used as markers of pulp wash. The methoxylated flavonoids sinensetin, nobiletin, 3,3',4',5,6,7,8-heptamethoxyflavone, 4',5,6,7-tetra-O-methylscutellarein and tangeretin in the samples were determined by HPLC on an ODS column with aqueous 40% acetonitrile as mobile phase and fluorescence detection with excitation at 330 nm and emission at 430 nm. An iterative program was used to compute the composition of the binary mixture from experimental results and known contents of flavonoids in original juices and aqueous extracts originating from different countries. A spectroscopic method is more commonly used but is not useful for mixed juice products. Orange juice samples were analyzed for pulp wash and dilution by measuring the absorbance sum at 443, 325 and 280 nm and the 443–325 nm absorbance ratio, and by fluorimetry at 310–423 nm with excitation at 230–340 nm (details given). The effect of adulteration of samples by dilution or by addition of pulp wash on the measured parameters is significant.

Capillary zone electrophoresis measurements of the minor anions in orange juice and orange pulp wash were made. Orange juice was diluted to 10° Brix and centrifuged. After filtration the anions were analyzed on an electrophoresis system with a fused silica column and an applied voltage of 20 kV. Range and mean results for orange juice, orange pulp wash and processing plant water could not be used to detect adulteration of orange juice with orange pulp wash.

Repeating another familiar pattern, isotope techniques have found use in authenticating orange juice. Site-specific isotopic content and stable isotope ratio have both found utility in detecting sugar addition. In an alternative approach, freeze-dried orange juice was mixed with hydrogen peroxide and centrifuged. The supernatant was mixed with trimethylsilylpropionic-2,3,3-d3 sulfonic acid Na salt (internal standard) and H NMR spectra were acquired at 400 MHz. The water signal was presaturated for 3 s with a low-power continuous-frequency radio wave. The free induction decays were multiplied with an exponential factor corresponding to 0.3 Hz in the Fourier-transformed spectrum and the spectra were normalized. The partial linear fit (PLF) data preprocessing tool was used to correct for variations in resonance positions between different spectra. With pattern recognition software, the method could discriminate between authentic and nonauthentic samples such as those to which beet sucrose or BMIS had been added.

Capillary GC analysis of oligosaccharides is another recurring theme that applies to orange juice. This procedure is based upon the detection of traces of maltotriose (DP3) and maltotetraose (DP4) which are absent from the sugar profiles of citrus fruits. Samples were centrifuged, filtered and preconditioned on C18 Sep-Pak™ cartridges. The samples were evaporated to dryness and the residue was dissolved in water–acetonitrile (7:13). The DP3 and DP4 carbohydrates were separated by LC on an aminopropyl silica gel column with water–acetonitrile (7:13) as mobile phase. The fractions containing DP3 and DP4 carbohydrates were evaporated to dryness and the sugars were converted into oxime-TMS derivatives and extracted into 2-mL isooctane which was injected on to DB-1 column. The detection limit was ~1 mg L⁻¹. The method can be applied to citrus fruit juices adulterated with sugar syrups but not crystalline sugar products.

NIR shows promise as a fingerprinting method for detecting adulteration of orange juice. Authentic and adulterated orange juice samples were vacuum dried at 45°C and 5.3 KPa for 9 h, then manually ground and sieved to 300 μm. The dried samples were placed in cells (50-mm diameter × 10-mm depth) with a quartz side-window, and were scanned. The reflectance spectra recorded over 1100–2498 nm at 2-nm intervals. Application of principal component and factorial discriminant analysis to these spectra can detect the adulteration of orange juice with an average accuracy of 90%.

### 6.10 Other Juices

As a final commodity group, other juices were selected by the ease with which they can be adulterated. Fortunately, the simple adulterants are easily detected. As before,
there are many recurring themes. It is a matter of application and data.

As a first example in this last subsection, researchers have developed a procedure to compare the $^{13}$C content of the sugars in a juice to that found in the fruit pulp.\(^{(116)}\) This is an internal standard approach and greatly improves the sensitivity to detecting adulteration in fruit juices. Samples were centrifuged to yield a pulp and supernatant or sugar fraction. The fractions were combusted to produce carbon dioxide and isotopic analysis was performed.

Another example with infra-red seems appropriate to illustrate the growing trend to deal mathematically with the water rather than dry samples. In this example,\(^{(117)}\) spectral measurements of raspberry purées prepared from fruit gathered in the 1993, 1994 and 1995 growing seasons were made using a FTIR spectrometer at 8-cm\(^{-1}\) resolution with 256 interferograms. Single beam ATR (attenuated total reflectance) spectra were collected for each sample, transformed to absorbance units using a background spectrum for water, and truncated to 235 data points in the region 899–1802 cm\(^{-1}\). This method follows the trend in being dependent on chemometrics for interpretation.

Wine has been used as an example in several places. It seems appropriate to mention a current concern. Red wines can be adulterated with other anthocyanin pigments. One study outlines a simple procedure for detecting elderberry pigments.\(^{(118)}\) For this procedure, red wine was extracted with a C\(_{18}\) Sep-Pak™ cartridge and washed with 1% formic acid. The anthocyanins were eluted with methanolic 1% formic acid and the eluant was concentrated under vacuum. The residue was dissolved and filtered before HPLC analysis on an ODS Hypersil™ column with gradient elution with aqueous 0.6% H\(_2\)ClO\(_4\)--methanol (4:1 to 12:13 over 32 min) and detection at 520 nm. The anthocyanins, cyanidin 3-sambubioside-5-glucoside, cyanidin 3-glucoside and cyanidin 3-sambubioside, were present in the elderberry extract, with the latter two co-eluting. The presence of these peaks in red wine indicated that it had been adulterated with elderberry pigments.

Pineapple is one of the more important minor fruits. It has also been adulterated substantially from time to time. One of the big problems is obtaining juice with the correct balance of sugar to acid. Such problems are easily remedied with either sugar or acids. Pineapple is a CAM plant, which makes the stable isotope methods less discriminating because of the intermediate $\delta^{13}$C values of pineapples. However, researchers have reported an HPLC procedure for the free sugars and detecting the addition of corn or cane sugars by detecting the presence of maltose.\(^{(119)}\) For this procedure, samples were blended with methanol and the resulting slurry was heated in a magnetic mixer for 20 min and centrifuged. The solutions were evaporated to small volume, diluted with water and applied to a Sep-Pak™ C\(_{18}\) cartridge. Part of the filtrate was mixed with acetonitrile and the solution was filtered. Samples prepared in this manner were analyzed on a Bondapak/carbohydrate column with aqueous 75% acetonitrile as mobile phase and UV detection. In natural samples, the ratio of I/II was found to be $\sim$1 and the maltose concentration was zero. The method was used for the analysis of suspected cases of adulteration of pineapple products.

Given the importance of the organic acids and titratable acidity to pineapple flavor, the addition of citric acid or malic acid has been a more common form of adulteration. HPLC has been used to measure these acids and can often detect adulteration.\(^{(120)}\) After using a sample preparation procedure similar to the above procedure for pineapple sugars, samples were analyzed by HPLC on a C\(_{18}\) column with detection at 214 nm. The main compounds identified by HPLC were citric and l-malic acid, with smaller amounts of oxalic, quinic and succinic acids. For most samples, the sum of these acids was close to the total titratable acid and the ratio citric acid:malic acid was close to 2:1.

The last two references consider berries. Berries are expensive and therefore prone to adulteration with less expensive materials. In the first case,\(^{(121)}\) adulteration of cranberry juice products by oenocyanin, a pigment from grapes, was detected by comparing HPLC profiles of cranberry anthocyanins with those from oenocyanin. The HPLC procedure used a reversed-phase styrene–divinylbenzene column in 10% acetic acid in water. Gradient elution was from 0% to 90% methanol–water–acetic acid (6:3:1). Both solvents were buffered to pH 1.6 with 3% H\(_3\)PO\(_4\). Detection was at 530 nm.

In the second case,\(^{(122)}\) blackcurrant adulteration by blackberries was detected by differences in the flavonol glycosides and flavonol glucuronides. Blackberries or blackcurrants were homogenized with methanol, filtered and concentrated. The residual solution was cleaned up on a polyamide column, from which flavonol glycosides were eluted with methanol, and flavonol glucuronides with methanolic 0.5% NH\(_3\). Each eluate was concentrated and filtered before HPLC analysis on a Hypersil™ ODS column. Ion chromatography of the flavonol glycoside eluate was necessary if adulteration by reedcurrants was suspected. Quercetin 3-O-$\beta$-glucuronide is absent from blackcurrants and is thus an indicator of adulteration by blackberries, an addition of 1% of blackberry juice being detectable. Quercetin 3-O-$\beta$-glucuronide is also present in grapes, but addition of grape juice can be identified by the detection of tartaric acid.
7 FUTURE TRENDS

The future of adulteration determination is likely to be a mix of more of the same and new methods. Adulteration is likely to be a concern as long as there are those who believe they can make extra money by providing deceitful alternative products. New methods based on profiling techniques are likely to become increasingly important as authenticators seek more discrimination power and lower costs. The world’s growing population and shrinking global marketplace will force scientists, regulators and food processors to standardize definitions for various commodities. These definitions need to be statistically based. The key for their development is networks that generate and share data for authentic samples. Without this data, outliers are indistinguishable from adulterated samples. It is only a matter of time until a new fraud is exposed that embarrasses one or more major food companies.

The increasing demand for foods that contain additional phytochemicals and other nutrients offers a new frontier for the deceitful and for those who strive to maintain a fair and honest marketplace. Elixirs and tonics are again entering the marketplace. New methods are required. New databases need to be developed. It will be interesting to see where the resources are found to meet these needs. Technical expertise to make and propose products is moving much faster than the ability to verify and test. However, it is unlikely that we will see a return of the truly dangerous forms of adulteration seen in past centuries.

ADULTERATION DETERMINATION

Atomic Spectroscopy in Food Analysis

Scott A. Baker and Nancy J. Miller-Ihli
US Department of Agriculture, Beltsville, USA

1 Introduction

Since food is the primary source of essential elements for humans, the accurate and precise analysis of food materials is critical. The methods best suited to meet this task are atomic spectroscopic methods such as atomic absorption, atomic emission, and elemental mass spectrometry (MS). Methods commonly used in the generation of food composition data include flame atomic absorption spectrometry (FAAS), graphite furnace atomic absorption spectrometry (GFAAS), inductively coupled plasma atomic emission spectrometry (ICP/AES), and more recently, inductively coupled plasma mass spectrometry (ICP/MS). FAAS and ICP/AES offer similar detection limits (DLs) (ng mL$^{-1}$ levels), whereas, GFAAS and ICP/MS can provide sub-ng mL$^{-1}$ detection capability. The choice of a method often depends on detection capability, but ease of use, speed of analysis, and cost must be considered. ICP/AES and ICP/MS offer the advantage of providing simultaneous multielement measurements, making them well suited for the analysis of large numbers of elements in food samples. If one or a few elements are to be determined, less expensive atomic absorption spectrometry (AAS) methods might be more suitable. The most critical stage in the development of analytical methods is sample preparation. Samples can be prepared using numerous procedures, but the most useful for a wide range of analytes and sample matrices are based on dry ashing or wet ashing of the sample. In addition to total element determinations, speciation measurements are important to determine the exact form of the element that is present in the sample. Since the bioavailability of an element is dependent on its chemical form (speciation), the development of reliable methods for identification and quantification of trace element species is critical. The coupling of chromatographic separation and atomic spectroscopic detection has proven useful for elemental speciation measurements.

1 INTRODUCTION

Since food is the primary source of essential elements for humans, the accurate and precise analysis of food materials is critical for consumers and health care professionals to make choices and recommendations based on the nutrient content of foods. Elements of interest include both major elements (e.g. calcium, sodium, potassium, magnesium, phosphorus, and chloride) and minor elements (e.g. iron, chromium, manganese, copper, zinc, cobalt, iodine, selenium, and molybdenum). The National Research Council has established the recommended dietary allowance (RDA) for seven elements (calcium, phosphorus, magnesium, iron, zinc, iodine, and selenium). Estimated safe and adequate daily dietary intakes have also been issued for five additional elements (copper, manganese, fluoride, chromium, and molybdenum) and estimates of requirement for three electrolytes (sodium, potassium, and chloride). Several additional trace elements are considered essential (arsenic, nickel, silicon, boron, and cobalt) or potentially essential (cadmium, lead, lithium, tin, and vanadium) but required levels have not been quantified.

In an attempt to provide nutritional information to consumers, the Nutrition Labeling and Education Act (NLEA) of 1990 mandated, for the first time, that labels on almost all processed food must contain the levels of 14 nutrients. Three of the mandatory nutrients...
are elements (calcium, iron and sodium). Thirty-four additional nutrients, 12 of which are elemental (potassium, phosphorus, magnesium, zinc, iodine, selenium, copper, manganese, fluoride, chromium, molybdenum, and chloride), which affect human health may currently be labeled voluntarily.

A review of the state of knowledge of food composition data demonstrates that there is a significant lack of data for specific food groups and for several of the elements of interest. This is due largely to the lack of suitable analytical methodology that can provide rugged, accurate elemental analyses of food matrices and the cost required to do large-scale sampling to obtain representative values. Because of mounting interest among health professionals and the public in the maintenance or promotion of good health and disease prevention, rather than diagnosis and curing of disease, reliable analytical data are increasingly important. This information can be used to assess the nutrient content of consumed foods and also for the establishment of the essentiality of elements that could play a role in the promotion of good health. The generation and compilation (such as in the US Department of Agriculture’s Nutrient Database for Standard Reference, SR-12) of reliable analytical data is critical as knowledge of the role of trace elements in human health is expanding. In addition, the role of trace element speciation in relation to absorption and metabolism has stirred greater interest in the development of techniques capable of providing not only total elemental content of foods, but also species-specific information. In many cases, speciation information is of primary importance, since only selected forms of the element are biologically active and absorption can be significantly affected depending on the chemical form.

The methods most suitable for the rapid and accurate determination of the elemental content of foods are atomic spectroscopic methods such as AAS and atomic emission spectrometry (AES). Challenges in the determination of metals and minerals in foods include the wide range of concentrations present, ranging from ng g\(^{-1}\) levels (e.g. chromium and cobalt) to percent levels (e.g. sodium and potassium), combined with the analyte and matrix specificity of many official methods. In addition, interest in identifying the essentiality of low-level trace elements in foods demands very sensitive and selective analytical methods. Methods commonly used in the generation of food composition data include FAAS, GFAAS, flame atomic emission spectrometry (FAES), ICP/AES, and more recently, ICP/MS. Although FAES can be and often is successfully used for the determination of sodium and potassium in foods, it is not discussed in this contribution because of its relatively limited applicability combined with the fact that these elements are also easily measured with more robust multielement techniques, such as ICP/AES and ICP/MS.

In this overview on the use of atomic spectroscopy in the analysis of foods, the characteristics and applicability of the various analytical methods will be discussed. The strengths and limitation of the various techniques will be highlighted and recently reported applications will be featured. In addition, sample preparation considerations will be discussed since this is often the most critical part of the complete analytical method. A section is also dedicated to trace element speciation because of the importance of this field in nutritional science, and also because of the many innovative methods and interesting applications that have been reported in recent years. The importance of quality assurance (QA) and the preparation/characterization of reference materials (RMs) will also be discussed. This is because successful implementation of new technology and new analytical methods depends largely on the effective use of QA quality control (QC) strategies, which, in turn, rely on the development and availability of well-characterized RMs.

2 SAMPLING AND SAMPLE PREPARATION METHODS FOR FOODS

2.1 Sample Collection and Processing

The suitability of the sample provided for analysis is an often-overlooked aspect in analytical determinations. Because proper selection and treatment of food samples is crucial, attention given to sampling must be at least as great as that given to the analyses. Too frequently, costly and time-consuming analyses are carried out on samples that have been improperly collected or handled, leading to suspect data and a waste of valuable resources. For a detailed discussion on sampling as it relates to the production of food composition data, the reader is referred to an excellent book by Greenfield and Southgate.

It is important that careful consideration be given to what information is to be provided by the analysis. For example, is it important to gain information on the variability of trace element content of food due to the season, climate, location, etc. or is information on the average content of the food (e.g. for food label values) of primary interest? Often work completed at the Food Composition Laboratory (FCL) (US Department of Agriculture, Beltsville Human Nutrition Research Center, Beltsville, MD, USA) is in support of the Nutrient Data Laboratory, which is responsible for publication of the US Department of Agriculture’s Nutrient Database for Standard Reference (SR-12). This publication serves as the primary database for US food composition.
data; therefore, the goal is to include data that are representative of the national food supply. Because of the expense of large-scale national samplings, a feasible and cost-effective alternative is to pick up samples from several different locations across the country with brands selected based on frequency of consumption, in order to gain as representative a sample as possible. Samples are brought into the laboratory and, depending on the form of the sample and the information desired, a decision is made either to analyze multiple samples or to combine samples and remove separate aliquots for analysis. The complexity and homogeneity of the sample will dictate what steps are needed to ensure that a representative sample is provided for analysis. Most often, a preliminary evaluation of the homogeneity of a select number of analytes in the material serves as a basis for selection of sample size and number of replicate samples that must be analyzed. Analyte concentration can be reported on an as received (fresh weight) or dry weight (moisture corrected) basis. To obtain the concentration on a dry weight basis, the measured concentration of a moisture-containing sample is divided by one minus the sample moisture. For example, if the sample moisture is 10%, the measured concentration is divided by 0.9 (1 – 0.1) to obtain the concentration on a dry weight basis. Moisture values are typically determined by drying samples (e.g. in a vacuum oven) until a constant weight is obtained.

Tools are generally available that facilitate sample homogenization without trace element contamination. Otherwise, specialized tools can often be custom produced. For cutting of food samples, titanium or high-purity glass knives can be used. Large-scale mixing devices (e.g. Robot-Coupe, Jackson, MS, USA) equipped with titanium blades and a plastic-lined bowl to avoid contamination have been used at the FCL for the blending and homogenization of QC samples including a diet RM (RM 8431 – Mixed Diet) sold by the National Institute of Standards and Technology (NIST). Plastic trays and storage containers are most often used to minimize trace element contamination. Elements that have a high potential for contamination include Al, Ca, Cr, Cu, Fe, Zn, and Sn. Sample storage containers should be selected based on potential for introducing contaminants while considering cost effectiveness. Although Teflon® containers present the lowest risk of contamination, less expensive polyethylene and polypropylene containers are generally adequate. Containers made of quartz or borosilicate glass are less desirable. During sample preparation (particularly for low-temperature (<100°C) wet ash preparations), glassware can be silanized to minimize the likelihood of contamination. The coating will be retained on the surface of the glassware to temperatures of approximately 350°C, providing excellent protection from contaminants being leached from the glassware due to the interaction of the sample matrix with the glass. In addition, silanization protects from loss of analyte due to adsorption on container walls.

During the sample processing stage, contamination can generally be controlled with good laboratory practices. In an ideal situation, samples can be processed in high-energy particulate air (HEPA) filtered clean rooms designed to have minimal contamination. Clean hoods and laminar air flow units can also prove useful and the analyst should consider common sense practices, such as wearing clothing and shoe protectors to minimize particulate generation, selecting powder free gloves, cleaning glassware and plasticware with dilute, high-purity acid, and covering gas cylinders that can produce metal contamination.

2.2 Sample Preparation

It is imperative that high-purity reagents be used for sample preparation to minimize trace element contamination. Sub-boiling distilled or doubly distilled acids are good choices for sample treatment when ultratrace determinations are required. For example, sub-boiling distilled nitric acid (Seastar Chemicals, Sidney, BC, Canada) contains very low levels of contamination: <50 pg mL\(^{-1}\) for Ca, <20 pg mL\(^{-1}\) for Fe; <10 pg mL\(^{-1}\) for K, Cr, Cu, Na, Mg, Ni, and Zn, and <1 pg mL\(^{-1}\) for Mn, Co, and V. Typical contamination levels in hydrochloric acid (Ultrex II, J.T. Baker, Phillipsburg, NJ, USA) are <500 pg mL\(^{-1}\) for Ca and Fe, <200 pg mL\(^{-1}\) for Cr and Ni, <100 pg mL\(^{-1}\) for Na and K, <50 pg mL\(^{-1}\) for Mg, V, and Zn, and <10 pg mL\(^{-1}\) for Co, Cu, and Mn. In addition to acid purity, all reagents used throughout the sample preparation and analysis provide potential sources of contamination and must be carefully evaluated.

Environmental considerations are equally as important as reagent purity when selecting a sample preparation method. If possible, samples should be handled in clean air conditions under laminar flow to prevent contamination. Potential sources of contamination include the analyst (particulate from skin or clothing), sample container and delivery material (e.g. pipets), air, gloves, metallic heating blocks, muffle furnaces, and various other sources. Due consideration must be given to the many potential sources of contamination if reliable quantitative results are to be obtained.

Most commonly, samples are introduced into atomic spectrometers as solutions. Depending on the sample matrix and analytes of interest, one of several procedures can be used to get samples (or analytes) into solution. These include extraction, dry ashing, and wet ash digestion. Wet ash digestions can either be done at atmospheric pressure on a hot plate or heating block, or at high pressure using a digestion bomb or by
microwave heating. These techniques will be discussed more thoroughly in the following sections. In addition, direct analysis can be accomplished in some instances either by simple dilution of the sample (e.g. with milk samples) or by slurry (or solids) analysis techniques. Sample preparation for direct and slurry analysis will be discussed in section 2.2.4.

2.2.1 Extraction

In some cases, a simple analyte extraction or leaching procedure using acidic solutions can be effective for food and biological samples. The success of these methods depends on the analytes of interest and the sample matrix. Azouzi et al. have reported a procedure for the room-temperature leaching of several elements from mussel samples using a solution of 1.6 M HNO₃, 1.2 M HCl, and 0.1 M H₂O₂. Samples of 200 mg were ultrasonicated in 10 mL of the acid mixture for 120 min, and determinations were carried out by either FAAS or GFAAS. The authors reported quantitative recoveries for Ca, Cu, Fe, K, Mg, Mn, Na, V, and Zn and partial recoveries (50–80%) for Cd, Co, Cr, Rb, and Se. Relative errors were lower than 9% when analyzing a certified reference material (CRM 278 Mussel Tissue).

Tetramethylammonium hydroxide (TMAH) and tertiary amines have been employed for the alkaline extraction of elements from biological and food samples. Mixed amines have been demonstrated to be useful for the complete extraction of Ca, Cu, Mg, Mn, Na, K, Zn, Mo, Rb, Se, Cr, and Zn from several RMs with detection by ICP/AES and ICP/MS. Samples (0.2 g) and 10 mL of 9.5% v/v mixed amines were magnetically stirred for 30 min at room temperature and then centrifuged to remove the solids. Materials studied include the NIST Standard Reference Material (SRM) 1577b Bovine Liver, 1566a Oyster Tissue, 1570a Spinach Leaves, 1567 Wheat Flour, and 1548 Total Diet. Unfortunately, low recovery values were observed for Al and Fe in all of the matrices and for Ca in spinach and apple leaves. The authors concluded that the low recoveries were probably the result of insoluble silicate compounds often retained in the inorganic matrix of plant tissues.

The use of TMAH extraction has also been reported for the determination of iodine in food samples with ICP/MS detection. Iodine is very susceptible to loss during sample preparation either by dry ashing, where an alkaline agent is necessary, or wet ashing, which requires addition of a strong oxidizing agent (e.g. HClO₄). As an alternative sample preparation technique, quantitative extraction of iodine from foods (e.g. milk powder, egg powder, and cod muscle) has been demonstrated using TMAH at elevated temperature (90°C) for 1 h in a sealed vessel. Samples of 0.2–0.5 g were used with 5 mL of water and 1 mL of 25% TMAH. The procedure was not successful for the extraction of iodine from an algae powder (≈75% recovery) unless particle sizes were reduced to less than 300µm. A similar TMAH extraction procedure was used for the determination of iodine in milk powders, bovine liver, and infant food. In comparing this extraction method with microwave-assisted digestion, it was concluded that although both methods provided accurate results, the extraction procedure was more time-consuming (2–3 h compared with 1 h for microwave digestion) and could not guarantee total extraction of iodine in all cases.

Although a simple extraction might be useful in some instances, it is not generally recommended. This is because recoveries are dependent on both the analyte and food matrix, making the technique of little utility in a laboratory that deals with a range of sample types. Better results can be expected if methods are developed using more reliable and complete dry ash and wet ash procedures.

2.2.2 Dry Ashing

Preparing samples by dry ashing is commonly used in the analysis of foods. Although the method is generally time-consuming, usually taking a day or more, it requires little attention from the analyst since samples are prepared in a batch mode. Ashing aids (e.g. magnesium nitrate) and modification of the sample matrix are often used to eliminate potential losses and/or speed up the ashing process; however, these can lead to contamination of the sample and poorer DLs. A benefit of dry ashing, compared with wet ash digestions, is that the resulting ash can be dissolved in a small amount of diluent. The small dilution factors possible with dry ashing offer the potential for improved DLs.

Results from a Nordic Committee on Food Analysis (NMKL) collaborative study on the determination of several metals (Pb, Cd, Zn, Cu, Fe, Cr, and Ni) in foodstuffs using dry ashing and AAS (flame and furnace) demonstrate the utility of the technique. In this method, 10–20 g samples (liver paste, apple sauce, minced fish, wheat bran, milk powder, and composite diets) were dried and then ashed overnight at 450°C. Then, 1–3 mL of H₂O was added and the temperature maintained at 450°C for several hours. This process was repeated until complete combustion was obtained (i.e. white/gray ash present). Hydrochloric acid (5 mL of 6M) was then added and the solution was evaporated to dryness. HCl is generally not recommended for GFAAS analyses because of the formation of volatile chlorides that can be lost during thermal pretreatment steps. The residue was dissolved in 0.1 M HNO₃ for AAS (flame and furnace) determinations. It was concluded by the authors that
no loss of Pb, Cd, Zn, Cu, Fe, and Cr occurred during the dry ashing since the measured values agreed with reference values; however, Ni determinations showed poor precision, probably owing to contamination.

2.2.3 Wet Ashing

Wet ash sample decomposition can be performed on a heating plate under ambient pressure,\(^\text{15,16}\) in a pressurized digestion vessel,\(^\text{16–19}\) or with open,\(^\text{20,21}\) and closed-vessel microwave heating.\(^\text{22–25}\) In a study involving the determination of Mn and Cr by AAS, Tinggi et al. used wet ashing performed on a heating plate to decompose effectively a variety of food samples (breads, cereals, meats, dairy products, vegetables, and fruits).\(^\text{15}\) In this method, 5–15 g of moist foods (or 1–2 g of dry) were placed in 150-mL flasks. An acid mixture of HNO\(_3\)–H\(_2\)SO\(_4\) (12 ± 2 mL) was added and left overnight. The next day, glass funnels were added to the flasks for refluxing and the mixture was heated. The appearance of white fumes of sulfur trioxide was used to indicate completion of the digestion. It should be noted that the authors also investigated the addition of HClO\(_4\) to the digestion mixture, but found it unnecessary to achieve complete digestion. Good reproducibility was reported with the HNO\(_3\)–H\(_2\)SO\(_4\) mixture, except for samples containing high levels of carbohydrate or fat. In these cases, it was necessary to use smaller sample sizes (1–2 g of wet food), increased digestion times, and additional HNO\(_3\). The accuracy of the method was verified by the measurement of NIST SRMs (SRM 1549 Non-fat Milk, SRM 1573 Tomato Leaves, and SRM 1577a Bovine Liver). Although some workers have reported difficulties with the determination of Cr in samples with appreciable silica contents (e.g. lettuce), necessitating the addition of HF, these authors reported that no statistical difference in measured concentrations was found when HF was added to the digestion mixture. Although these results indicate the suitability of open-vessel wet ash digestion for the determination of trace elements in some instances, there are drawbacks. They are time-consuming, subject to analyte contamination and loss, and might not be vigorous enough to ensure complete decomposition of some matrices. For this reason, high-temperature and/or high-pressure methods are often preferred.

Microwave sample digestion is a growing field and the number of analysts using this sample preparation tool has increased considerably in the last decade. An excellent source of information on the principles and application of microwave sample preparation is the book by Kingston and Jassie.\(^\text{26}\) It must be noted that as a safety issue, specially designed laboratory microwave ovens rather than household microwave ovens must be used for procedures since corrosive fumes can severely damage the devices and lead to an explosion. Although microwave digestion can be a rapid and reliable means of sample decomposition with relatively minor risk of contamination, care must be taken when analyzing samples with a variety of matrices. This is because, depending on the carbohydrate content of the samples, pressures will build up at different rates and require venting at different times. For this reason, microwave digestion systems that are capable of monitoring temperature and pressure in each vessel, such as the Perkin-Elmer Multiwave (Perkin-Elmer Corp., Norwalk, CT, USA), are essential if different types of foods are to be analyzed at the same time. Use of this system for the decomposition of a wide range of food samples has been reported.\(^\text{27}\) Samples (nuts, eggs, cream, cheese, etc.) of 0.4–0.7 g were placed in high-pressure quartz digestion vessels and 5 mL of concentrated HNO\(_3\) was added. Vessels were sealed and heated according to the following program: stage 1, ramp from 100 to 600 W in 5 min; stage 2, hold at 600 W for 5 min; stage 3, 1000 W for 10 min; and stage 4, 0 W for 15 min. Samples were then opened and diluted in water for analysis. Digested samples were analyzed by ICP/AES for NLEA mandatory and voluntary elements. Results for several food SRMs (milk powder, spinach, corn, total diet, etc.) were in good agreement with certified values.

Wu et al. investigated a microwave digestion method using HNO\(_3\) or a mixture of HNO\(_3\) and H\(_2\)O\(_2\) for the preparation of plant and grain RMs for ICP/MS measurements.\(^\text{23}\) The use of HNO\(_3\) as a digestion medium is typically preferred for ICP/MS measurements since this acid introduces few spectral interferences. Although HClO\(_4\) and H\(_2\)SO\(_4\) are also used as oxidants, there are drawbacks to their use including the production of a number of spectral interferences and they are also an additional potential source of contamination. Perchloric acid can also be extremely dangerous, whereas H\(_2\)SO\(_4\) can form sparingly soluble sulfates that can precipitate from solution. The method used by these researchers involved weighing 0.5 g (dry mass) of sample in a Teflon\textsuperscript{®} digestion vessel and adding 2.5 mL (grain samples) or 5.0 mL (plant samples) of concentrated HNO\(_3\). The mixture was then allowed to sit overnight prior to microwave digestion. A maximum of 12 samples were digested according to the following program: heat to 165 °C within a ramp time of 10 min at 1000 W; hold for 20 min at 165 °C under a maximum pressure of 13.8 bar (200 psi). After digestion, samples were diluted in water to a final HNO\(_3\) concentration of 2% v/v. For the HNO\(_3\)–H\(_2\)O\(_2\) digestion, 2–5 mL of H\(_2\)O\(_2\) (30% v/v) was added to the digestion mixture prior to microwave digestion. The presence of H\(_2\)O\(_2\) helped to maintain a higher temperature under the pressure limit (13.8 bar) and reduced the carbon content in the digestates, but its impurities limited the determination of some elements at low levels. For grain
RM. The majority of recoveries for the 26 elements determined were within 85–115%. For plant SRMs, the majority of recoveries were within 70–115%, but were only 40–80% for Ni, Th, Ti, and U. The authors attributed the low recoveries to siliceous material that was not completely decomposed during digestion.

Some interesting modifications of traditional microwave digestion technology can be found in the literature. Deaker and Maher reported a low-volume microwave digestion method for the determination of Se in biological tissues by GFAAS. Small samples (0.025–0.1 mg) and 1 mL of HNO₃ were placed in 7-mL screw-top Teflon vessels. Two of these vessels were then placed into larger 120-mL digestion vessels. Twelve of these traditional, larger vessels could be loaded into the microwave cavity at once. The optimized microwave program was 600 W for 2 min, 0 W for 2 min, and 450 W for 45 min. Quantitative recoveries of selenium from several RMs (oyster tissue, albacore tuna, fish flesh, etc.) were obtained using this method. Recently, Levine et al. evaluated a high-pressure, high-temperature focused microwave digestion system (BM-1S/II, Plazmatronika, Wroclaw, Poland) for the determination of 18 elements in different RMs including four food-related materials (peach leaves, orchard leaves, oyster tissue, and bovine liver) by ICP/AES and GFAAS. Compared with traditional microwave digestion systems, the focused system employing tetrafluoromethoxil polymer digestion vessels (TFM-PTFE) can accommodate higher temperatures (350°C) and pressures (up to 160 bar). This should result in more complete destruction of organic matrix constituents using only HNO₃ as the digestion medium. By comparing GFAAS background absorbance and liquid chromatographic analysis of nitrobenzoic acid decomposition products, the authors concluded that the new system provided more complete destruction of the sample matrix. The high-pressure, high-temperature system also produced more accurate results for metals in the RMs (average error 7.1% in mean recovery values compared with 11.8% for the traditional system).

2.2.4 Direct Analysis and Slurry Sampling

Direct analysis (including simple dilution) of food samples offers a number of potential advantages. Advantages include reduced sample preparation time, decreased potential for analyte loss, reduced risk of contamination from reagents because less sample handling and fewer reagents are required, elimination of hazards associated with the use of strong acids and other corrosive reagents, and the potential for improved sensitivity since samples are not as dilute. Two categories of sample preparation for direct analysis are considered in this section. One involves the simple dilution of samples that are, more or less, solubulized (e.g. for beverages). The other method involves the preparation of a slurry or suspension of solid samples in a liquid diluent.

Arruda et al. reported a method for the direct analysis of milk for Al using GFAAS. Samples (5 mL) were diluted to 15 mL with 0.2% v/v HNO₃ for analysis. Determinations using this sample preparation method were compared with results obtained by both dry ashing and wet ashing. Good agreement was reported and the accuracy of the method was verified by analyzing a milk RM. A procedure for the direct determination of major (Ca, K, Mg, Na, and P) and minor (Zn, Al, Ba, Cu, I, Mn, Mo, Pb, Rb, Se, and Sr) elements in milk by ICP/AES and ICP/MS using mixed tertiary amines has also been published. Typically, the analysis of milk by direct nebulization of aqueous solutions in inductively coupled plasma (ICP) spectrometric methods is plagued by poor sensitivity and accuracy. The poor performance has been attributed to milk’s fatty nature and the existence of large droplets that cannot be completely vaporized in the plasma. In addition, the chemical form of the analyte element (existing in aqueous phase, casein micelles, etc.) may also be critical. In the method presented, 0.1 g of powdered milk (or 1 mL of liquid milk) was dissolved in 10.0 mL (or 9.0 mL) of 10% v/v mixed amine reagent at pH 8 for ICP/AES measurements. For ICP/MS measurements, 0.2 g of powdered milk (or 2.5 mL of liquid milk) was dissolved in 49.5 mL (or 47.0 mL) of 5% mixed amine reagent at pH 8. It was stated that the mixed amine appeared to promote the total or partial dissolution of casein micelles, increasing the metal concentration in the aqueous phase. This led to improved performance compared with earlier milk analysis by ICP/AES, which were plagued by analyte insolubility in alkaline solutions or problems in the nebulization and atomization of milk slurry particles. The accuracy of the proposed method was verified by the analysis of milk SRMs. The values obtained agreed with the certified values at the 95% confidence level.

Flow injection analysis can be useful for the direct analysis of food and beverage samples. A review on the application of flow injection in atomic spectrometry by Burguera and Burguera demonstrates the versatility of the technique, such as for on-line dilution, dissolution, liquid–liquid extractions, and ion-exchange pre-concentration. Flow injection was used by Baxter et al. for the multielement analysis of wines by ICP/MS. Wine samples (5.0 mL) were diluted 1 : 1 with sample diluent (1.0% HNO₃) prior to analysis. Injections of 0.5 mL were introduced into a 1.0-mL carrier stream composed of 5.0% ethanol and 0.5% HNO₃. The method was verified by spike recovery experiments where all values were within 100 ± 25% and by analysis of provisional RMs produced by the Community Bureau of Reference (CBR).
The effect of ethanol concentration on the analyte signal was investigated and it was reported that only minor variations of ±10% were observed, making the method applicable to a range of alcohol contents in wines. The data were used to determine the origin of various Spanish and English wines.

Solid samples can be analyzed directly by preparing them as slurries or suspensions. These samples can then be nebulized into a flame (for FAAS) or plasma (for ICP/AES/MS), or alternatively, deposited in a graphite tube for GFAAS or electrothermal vaporization (ETV) ICP/AES/MS measurements. The benefit of the latter techniques employing graphite tubes is that residence times are much longer, leading to improved atomization/vaporization and fewer problems related to particle size effects. Slurry sample introduction for GFAAS and ETV/ICP/AES/MS is straightforward and can be automated using commercial autosamplers. This is especially advantageous for routine determinations. Numerous applications of slurry GFAAS and ETV/ICP/AES/MS can be found in the literature and specific applications will be discussed later.

Most food samples must be ground into smaller particles prior to analysis. This can be accomplished by freeze-drying samples and then shattering them in a ball-mill device or using wet grinding. A wet grinding method used in this laboratory involves adding samples and Teflon® beads (10:1 mass ratio of beads to sample) to polyethylene bottles. Approximately 10–15 mL of water or dilute HNO₃ are added to the bottles and the mixture is shaken for 2 h.

A general procedure for slurry preparation is provided here; however, readers are encouraged to consult the literature for a more complete treatment of factors (e.g. particle size, density, analyte distribution, mode of mixing) that must be considered for optimizing slurry preparations. Samples (typically 1–50 mg) can be weighed directly into autosampler cups to avoid problems that can result from the transfer of small quantities of sample. Although a variety of diluents have been used, the authors have found a mixture containing 5% v/v sub-boiling distilled HNO₃ and 0.005% Triton X-100® surfactant (Rohm and Haas registered trademark for octylphenoxypolyethoxyethanol; Sigma Chemicals, St Louis, MO, USA) to be useful for a range of sample types. Nitric acid facilitates the extraction of analyte into the liquid phase of the slurry; whereas, Triton X-100™ serves as a wetting agent and assists in particle dispersion. If particle coagulation is not problematic and/or analyte extraction is not desirable (e.g. in homogeneity characterizations), deionized, distilled water can be used as the diluent. In some cases, it might be necessary to prepare larger masses and/or volume slurry preparations. This can be done by placing sample and diluent in polyethylene tubes, then vortexing the mixture while a smaller aliquot is removed for the autosampler cup.

### 3 MEASUREMENT TECHNIQUES

Several factors should be considered when selecting an appropriate measurement technique. These factors include detection capability, ease of use, availability of instrumentation, speed of analysis, and cost. One must consider the relative importance of the factors for their particular application; however, detection capability is often a primary concern. A good general rule in selecting a method is to use the simplest method possible that meets the analysis requirements. For example, if the goal of an analysis is to determine µg mL⁻¹ (ppm) levels of metals in a beverage sample, the analyst should check to determine if it can be analyzed by simple dilution and measurement by flame AAS or simultaneous multielement ICP/AES (if more than a few elements are to be determined). Most trace element determinations in foods are accomplished by a handful of atomic spectroscopic techniques. These techniques are FAAS, GFAAS, ICP/AES, and, more recently, ICP/MS. Since a detailed description (including fundamentals and applications) of each of the methods is provided elsewhere in this Encyclopedia, only a brief description of the techniques is provided here. Basic principles of the methods and applications related to the determination of metals in foods will be reviewed in this section. A comparison of some of the important attributes associated with the measurement techniques under consideration can be found in Table 1.

3.1 Atomic Absorption Spectrometry

AAS is the most widely used technique for the determination of metals. A detailed discussion of AAS principles, instrumentation, and applications can be found in several books devoted to the subject.\(^{37,38}\) In this technique, the absorption of radiation by neutral, ground-state atoms is measured to determine the amount of analyte present in the sample. Radiation sources for AAS include the hollow-cathode lamp (HCL) and the electrodeless discharge lamp (EDL), whereas atomization is accomplished with a flame (typically air–acetylene or nitrous oxide–acetylene) or an electrothermal atomizer [electrothermal atomization atomic absorption spectrometry (ETAAS), also known as GFAAS]. AAS determinations are usually made by FAAS when the concentration of analyte is high enough, or by GFAAS when concentrations are low. When the detection capability is adequate, FAAS should be selected whenever possible because it is less time-consuming and also less sensitive to interference effects (e.g. from background absorbance) than GFAAS. Advantages of AAS are the potential for very high sensitivity (e.g. mini-gas flows during furnace atomization). A disadvantage is that AAS is primarily a single-element technique, although continuum-source and sequential AAS systems have been developed. In addition, the linear range is typically less than two orders of magnitude, requiring the use of alternative, less sensitive wavelengths or some other means of reducing sensitivity (e.g. mini-gas flows during furnace atomization).

### 3.1.1 Flame Atomic Absorption Spectrometry

FAAS is a well-established technique for the analysis of trace metals in food samples. It is estimated that 80% of all currently available trace element food composition data are the result of FAAS analyses after either wet ashing or dry ashing sample pretreatment. FAAS is a simple and robust tool for the analysis of a wide range of elements and calibration can typically be accomplished using a 3–5-point calibration curve made with aqueous standards. Because of the robustness (i.e. maturity) of the technique, relatively few new FAAS methods are being published in the analytical literature. This is not to say that interesting work is not being done in this area and several of the recently reported applications of FAAS in the analysis of foods\(^{6,15,39–41}\) or food-related materials\(^{42}\) are presented here.

The determination of Ca, Cu, Fe, Mg, and Zn in mussels by FAAS was recently reported.\(^{6}\) Samples were prepared for analysis by ultrasound extraction in a mixture of HNO\(_3\), HCl, and H\(_2\)O\(_2\) and analyzed using FAAS at 422.6 nm (Ca), 324.8 nm (Cu), 248.8 nm (Fe), 285.2 nm (Mg), and 213.9 nm (Zn) with an air–acetylene flame. The method provided a DL, defined as \(3\sigma_{\text{blank}}\), of 0.081, 0.012, 0.059, 0.002, and 0.007 µg mL\(^{-1}\) for Ca, Cu, Fe, Mg, and Zn, respectively. Relative standard deviation (RSD) values ranged from 0.6 to 7.1% \((n = 8\) analyses). In discussing the figures of merit for this and other techniques, it is important to remember that these values are dependent on a number of variables including the instrumental measurement, the sample preparation procedure including reagent contamination levels, and the sample matrix.

The essentiality of Mn and Cr for humans is well established; however, requirements or levels of absorption for adults have not been clearly determined. These questions can only be answered when accurate and reliable data on concentrations of these elements in foods are available. A method for the determination of Mn by FAAS (and Mn and Cr by GFAAS) at 279.5 nm was reported using an air–acetylene flame.\(^{15}\) Wet ashing was used to prepare a wide variety of samples for analysis. Relatively high levels of Mn (>10 µg g\(^{-1}\)) were found in most cereal products, whereas meats, dairy products, vegetables, and fruits contained low levels of the element. The accuracy of the FAAS method was verified by analyzing NIST SRM 1573 Tomato Leaves and NIST SRM 1577a Bovine Liver; recoveries were 95 and 98%, respectively. The precision (RSD) of these measurements was 3% \((n = 5–6)\) for Mn and the DL, based on a 2.0-g sample in a 20-mL final volume, was 0.15 µg g\(^{-1}\) (solution DL 0.015 µg mL\(^{-1}\)).

Although the importance of Se in the human diet is well established, the range between safe intake and toxicity is narrow, making accurate and reliable methods of analysis critical. Se determinations by traditional FAAS suffer from a relatively poor DL (around 1 µg mL\(^{-1}\)); however, hydride generation (HG) sample introduction can be used to achieve sub-parts per billion DLs for this element.\(^{41}\) The determination of Se in dairy foods and drinks by HG AAS has been reported and the data used to estimate the daily dietary intake of Se in the normal Spanish diet from these food sources.\(^{41}\) Samples were wet ashed with concentrated HNO\(_3\) and HClO\(_4\) then Se\(^{6+}\) was reduced to hydride forming Se\(^{4+}\) by addition of concentrated HCl. The standard additions method was used for calibration. RSD values \((n = 7,\) measurements of three random samples) ranged from 5% to 13% and the DL \((3\sigma)\) was 0.210 ng mL\(^{-1}\). The accuracy of the method was checked by spike recovery for three random samples and ranged from 97% to 106%. Of the dairy products studied, the highest levels of Se were found in aged cheese with concentrations ranging from 86 to 366 ng g\(^{-1}\) (wet-weight basis). The mean Se concentration was 164 ng g\(^{-1}\). The highest level of Se in various alcoholic...
and nonalcoholic drinks was found in pineapple juice (mean concentration of 2.88 µg L⁻¹).

### 3.1.2 Graphite Furnace Atomic Absorption Spectrometry

GFAAS provides sub-parts per billion detection capability using microliter-sized samples deposited in a graphite tube. The graphite tube is resistively heated to temperatures of up to 2800 °C to produce a dense cloud of atomic vapor. Traditionally, samples have been introduced into the graphite furnace as solutions; however, direct solid and slurry sampling have also been employed. The technique is a versatile and highly sensitive means of analysis for a wide range of sample types. The success of GFAAS can largely be attributed to the development of the stabilized temperature platform furnace (STPF) concept. The STPF approach employs a platform furnace so that the analyte is atomized in a more isothermal environment. STPF also provides for matrix modification for analyte stabilization, rapid furnace heating, pyrolytic graphite-coated tubes to reduce chemical interferences, good background correction (such as the Zeeman effect), no gas flow during atomization, and integrated absorbance measurements for quantification. Employing these conditions can significantly improve the quality of GFAAS analyses, allowing the technique to be used routinely for the determination of trace elements. Most often, calibration (even for slurry samples) can be performed with aqueous standards. The wide range of applications that have been reported in the literature demonstrates the versatility of the method.

Chromium is one of the essential trace elements in the human body and is typically found at low levels in foods. Soil contamination is an important factor contributing to the total Cr concentration in plant tissues because of uptake of this element. Because excessive levels of Cr (particularly Cr⁶⁺) in the human diet can cause adverse effects, monitoring of foods grown in areas of suspected contamination is necessary. The determination of Cr in wine and grapes by GFAAS was reported by a team of French and Spanish investigators since these foods could be a significant source of the element in a typical diet. Wine samples were analyzed directly, whereas, grapes were microwave digested in a mixture of HNO₃, H₂O₂, and HClO₄ prior to analyses. Cr was measured at 357.9 nm and the furnace program included a 1000 °C char step (no modifier) and an atomization temperature of 2600 °C. Calibration with aqueous standards was used for quantification. The suitability of analyzing wine samples directly was assessed by comparing concentrations determined with those obtained by dry ashing the samples. The accuracy of the GFAAS method was validated by spike recovery experiments (mean recovery 99.3% for four determinations in two different samples). The precision of the method (%RSD) was between 1.8 and 9.0% for six determinations in five different samples and a DL of 1.8 pg (0.09 ng mL⁻¹) was reported. Chromium concentrations were determined in a total of 79 wine samples and 12 grape samples. The levels were in the ranges 7–90 µg L⁻¹ in red wines, 6.6–43.9 µg L⁻¹ in white wines, 7.3–14.7 µg L⁻¹ in rosé wines, and 10.5–36.0 µg L⁻¹ in champagnes. Concentrations in grape samples were in the ranges 2.5–20.9 µg kg⁻¹ for white varieties and 2.4–64.6 µg kg⁻¹ for red varieties. The daily contribution from wine consumption in France was estimated to be 4.06 µg per resident, which is less than 10% of the daily dietary intake.

Pfiifer at the US Food and Drug Administration developed a method for the determination of Cr (357.9 nm) and Mo (313.3 nm) in medical foods (enteral formulas) by GFAAS. Samples were prepared for analysis by dry ashing. Both Cr and Mo were atomized off the wall of the graphite tube and neither analyte required the use of a chemical modifier. Optimum charring temperatures were 1600 and 1650 °C for Cr and Mo, respectively. Atomization temperatures of 2400 °C and 2650 °C proved optimum for Cr and Mo, respectively. Calibration with aqueous standards was performed and the method was validated by analyzing four NIST SRMs (SRM 1572 Citrus Leaves, SRM 1566a Oyster Tissue, SRM 1577a Bovine Liver, and SRM 1568 Rice Flour). Results for all of the materials analyzed were within the certified concentration ranges. The reproducibility of the method (%RSD) determined for one medical product, containing 0.31 ± 0.02 µg g⁻¹ Cr and 0.63 ± 0.03 µg g⁻¹ Mo, was 6.8% for Cr and 4.8% for Mo (n = 5 measurements). Reported DLs (3σ) were 0.36 ng mL⁻¹ for Cr and 1.0 ng mL⁻¹ for Mo.

GFAAS has frequently been employed for the determination of Se in food samples. A method for the determination of Se in infant and enteral formulas by dry ash sample preparation and GFAAS detection has been developed. Samples were ashed with the aid of HNO₃ and magnesium nitrate, then HCl (5 + 1) was added to dissolve all of the ash and reduce Se⁶⁺ to Se⁴⁺. Se⁴⁺ was subsequently reduced to Se⁰ with ascorbic acid and collected on a membrane filter. Filters were then microwave digested in HNO₃, diluted in water, and analyzed by GFAAS. The reason for the Se conversion was to isolate it from the dissolved ash, a step that was essential since only deuterium background correction was available. Nickel nitrate was used as a chemical modifier and the optimum charring and atomization temperatures were 1100 and 1800 °C respectively. Several RMs (Mixed Diet, Corn Bran, Milk Powder, etc.) were analyzed with the proposed method and measured concentrations were within the concentration range for each of the samples. Measured Se concentrations in
12 different infant and enteral formulas ranged from 2.9 ± 2 µg kg⁻¹ (n = 6 determinations) for a nonfortified infant soy formula to 191 ± 7 µg kg⁻¹ (n = 4 determinations) for a fortified infant milk-based powder. A DL (3σ) for Se of 0.44 ng mL⁻¹ was reported.

As mentioned previously, GFAAS can also be used for the analysis of slurry samples. Recent applications of slurry sampling GFAAS for the analysis of food include the determination of Cr in tomato leaves, Cr, Co, and Ni in vegetables, Mo, Al, Cr, and Mn in milk powder, Se in fish samples, and Cd, Cu, Fe, Pb, and Se in fruit. Because of the relatively large amount of solid being vaporized in the graphite tube, matrix effects can be problematic. The presence of organic material, not completely removed during the charring step, affects the volatility of some elements, increases background levels, and leads to the build-up of carbonaceous material in the furnace. To alleviate these problems, chemical modifiers can be used to stabilize volatile elements during furnace heating and good background correction methods (e.g. Zeeman or Smith–Hieftje) should be employed. Effective methods for removing carbonaceous material and thus avoiding its deleterious effects include the use of an oxygen or air ashing step in the furnace program or addition of H₂O₂ to the slurry diluent.

Chromium, cobalt, and nickel are typically found at very low concentrations in vegetables, the primary sources of these elements in the human diet. Because concentrations are low, very sensitive detection methods such as GFAAS must be employed for their determination. Carlosena et al. compared several sample preparation methods (dry ashing, slurry preparation, and continuous-flow microwave-assisted digestion) for the determination of Cr, Co, and Ni in vegetables. For slurry analyses, samples were ground in a household grinder and then a mortar and pestle before they were dried for 60 min, then samples were separated from the beads and diluted in water for analysis. It was reported that the grinding procedure ensured that 90% of the particles had diameters of <25 µm. The relatively fine particle size and low density of the samples allowed for manual shaking of the samples to be used to ensure that particles did not settle out prior to sample injection. Optimum charring and atomization temperatures for the analytes were 700 and 2000 °C for Cd (NH₄H₂PO₄ as modifier), 1000 and 2300 °C for Cu (no modifier), 1400 and 2400 °C for Fe [Mg(NO₃)₂ as modifier], 500 and 2100 °C for Pb (no modifier), and 1000 and 2200 °C for Se [Ni(NO₃)₂ as modifier]. Aqueous calibration was employed for all determinations and the accuracy of the method was validated using NIST SRM 1572 Citrus Leaves, spike recovery, and comparison with results obtained using microwave digested samples. DLs (3σ) were 0.3 ng g⁻¹ (0.024 ng mL⁻¹) for Cd, 3.5 ng g⁻¹ (0.04 ng mL⁻¹) for Pb, and 10.0 ng g⁻¹ (0.8 ng mL⁻¹) for Se. Precision values (%RSD) for 10 replicate determinations on each of five different samples ranged from 3.5 to 7.0%. The method was used for the analysis of eight types (five samples per type) of fruit samples (strawberry, medlar, banana, papaya, kiwi, mango, custardapple, and pineapple). Mean determined concentrations (fresh weight of edible portion) ranged from 0.3 to 50 ng g⁻¹ for Cd, from 0.337 to 1.094 µg g⁻¹ for Cu, from 2.00 to 5.50 µg g⁻¹ for Fe, from 0.050 to 0.396 µg g⁻¹ for Pb, and from 10 to 20 ng g⁻¹ for Se.

3.2 Inductively Coupled Plasma Atomic Emission Spectrometry

ICP/AES is a powerful technique for the determination of trace elements in foods. An excellent source of information on the fundamentals and some applications of ICP/AES is the book edited by Montaser and Golightly. In this technique, samples are introduced into a high-temperature (7000–8000 K) argon plasma where they are efficiently vaporized, atomized, and
excited. The emission of excited atoms is then measured to determine the quantity of analyte present in the sample. One of the major advantages of ICP/AES over AAS techniques is that it is capable of simultaneous multielement analysis, offering the potential for greater sample throughput. In addition, ICP/AES offers a linear dynamic range of five orders of magnitude or greater (compared with two orders of magnitude for AAS) making it useful for determining both macro and micro constituents of the sample. The DLs for ICP/AES are similar to those for FAAS and typically poorer than those for GFAAS by one or two orders of magnitude; however, the use of axially viewed ICP/AES systems has narrowed the gap. Because of the multielement capability and generally adequate detection capability, ICP/AES is becoming increasingly popular for the determination of trace elements in foods.

Negretti de Brätter et al. used ICP/AES for the determination of Al, Ca, Cu, Fe, K, Mg, Na, P, and Zn in total diet samples. One of the purposes for the study was to compare mineral and trace element intake for Venezuelan populations where a high incidence of stomach cancer exists and for populations where there is a low rate of incidence. Homogenized samples were digested using a high-pressure wet digestion method with HNO3 and H2O2 (2 + 1). Analytes were measured simultaneously at the following wavelengths; 396.15 nm (Al), 324.75 nm (Cu), 766.49 nm (K), 589.59 nm (Na), 213.86 nm (Zn), 393.37 nm (Ca), 259.94 nm (Fe), 279.08 nm (Mg), and 214.91 (P). Analysis of NIST SRM 1548 Total Diet was used to confirm the accuracy of the proposed method. Results for all of the elements except for K were within the certified concentration range. Results for K were 11% low compared with the mean certified concentration and it was assumed that this was caused by absorption of K by the Teflon® cover of the digestion vessel. The DLs (3σ) for the ICP/AES method were 37 µg kg⁻¹ (Zn), 2400 µg kg⁻¹ (P), 7.3 µg kg⁻¹ (Fe), 1.64 µg kg⁻¹ (Mg), 2.5 µg kg⁻¹ (Cu), 0.72 µg kg⁻¹ (Ca), 12 µg kg⁻¹ (Al), 40.5 µg kg⁻¹ (Na), and 490 µg kg⁻¹ (K). Results for the mean daily intake of the population investigated for the high stomach cancer incidence area (n = 77) as compared with the low incidence area (n = 33) showed significantly higher daily intakes for Na (2082 versus 1471 mg), K (1190 versus 731 mg), and P (640 versus 381 mg) and significantly lower intakes for Ca (925 versus 1379 mg) and Cu (2.78 versus 4.66 mg). No differences were obtained for Al, Fe, Mg, and Zn.

A Spanish group recently used ICP/AES for the characterization of green coffee varieties. Eleven metals (Zn, P, Mn, Fe, Mg, Ca, Na, K, Cu, Sr, and Ba) were chosen as chemical descriptors and pattern recognition techniques, such as principal component analysis and cluster analysis, were applied to characterize arabica and robusta coffees. Samples were wet ashed using a mixture of HNO3 and H2SO4 prior to analysis. Elements were determined at the following wavelengths: 213.86 nm (Zn); 214.91 nm (P); 257.61 nm (Mn); 259.94 nm (Fe); 279.55 nm (Mg); 393.37 nm (Ca); 589.59 nm (Na); 766.49 nm (K); 324.75 nm (Cu); 407.77 nm (Sr); and 455.40 nm (Ba). Significant differences were found in the metallic content of the two coffee varieties. The largest differences were found with P, Mn, and Cu, making these elements suitable for characterizing the two coffee varieties. Determined concentrations were 1410–2200 µg g⁻¹ for P, 14.5–47.9 µg g⁻¹ for Mn, and 14.3–76.9 µg g⁻¹ for Cu.

The determination of metals in food and biological samples with an axially viewed ICP/AES system using both a conventional concentric nebulizer and a microconcentric nebulizer has been reported. Seventeen elements were determined in three microwave-digested RMs (CBR CRM 63 Milk Powder, CRM 185 Bovine Liver, and CRM 278 Mussel Tissue). Elements were determined at the following wavelengths: 328.07 nm (Ag); 396.15 nm (Al); 193.70 and 188.98 nm (As); 614.17 nm (Ba); 317.93 nm (Ca); 228.80 nm (Cd); 228.62 nm (Co); 267.72 nm (Cr); 327.40 nm (Cu); 259.94 nm (Fe); 769.90 nm (K); 279.81 nm (Mg); 257.61 nm (Mn); 819.48 nm (Na); 231.60 nm (Ni); 220.35 nm (Pb); 346.45 nm (Sr); and 213.86 nm (Zn). Measured DLs were typically better with the conventional nebulizer than the microconcentric nebulizer, but the magnitude of the difference was element dependent. For the elements studied, DLs (3σ) ranged from 0.05 ng mL⁻¹ (Mn) to 30.48 ng mL⁻¹ (Ca) for the conventional nebulizer and from 0.13 ng mL⁻¹ (Mn) to 173.66 ng mL⁻¹ (Na) for the microconcentric nebulizer. Results for the analysis of RMs were in good agreement (t-test used) with the certified values, except for a few cases. It was concluded that either nebulizer could be used to obtain both accurate and precise results; however, the microconcentric nebulizer gave poorer sensitivity and was more susceptible to a deterioration in analytical performance when high-salt matrices were analyzed.

3.3 Inductively Coupled Plasma Mass Spectrometry

In the last decade, ICP/MS determinations have started to play a significant role in the generation of food composition data. The technique involves the detection of ions extracted from a high-temperature argon plasma. ICP/MS provides multielement, isotopic data with sub-ng mL⁻¹ DLs with the same convenience of FAAS or ICP/AES and much faster than GFAAS. As interest in low-level trace element concentrations continues to grow, the role of ICP/MS in the analysis of food samples will continue to expand. An excellent source of information on ICP/MS is a recently published book edited by Montaser.

In addition, Crews has published a review article that
deals specifically with the determination of trace elements in foods using ICP/MS detection. The article discusses a range of topics, including instrumentation, interferences, matrix effects, applications, and speciation measurements that utilize ICP/MS detection. Advantages of ICP/MS include excellent sensitivity and selectivity, simple spectra, wide linear dynamic range (6–7 orders of magnitude), and the ability to acquire rapidly multielement and isotopic information. The disadvantages of ICP/MS include costs (although they are becoming increasingly competitive) and a relatively low tolerance to total dissolved solids and susceptibility to matrix effects. Although mass spectra are much simpler than emission spectra, some spectral interferences (isobaric overlap, overlap from polyatomics, and doubly charged species) do exist and must be accounted for. In addition, a number of nonspectral interferences can occur, such as transport effects, ionization interferences, and ion sampling effects. Internal standards are frequently employed for ICP/MS determinations to account for nonspectral interferences; however, care must be used in selecting a suitable internal standard. Ideally, the internal standard should be similar in both mass and ionization potential to the analyte or analytes of interest.

The high sensitivity of ICP/MS is illustrated in Table 2, which gives DLs for several elements obtained for wet ashed total diet samples. The reference on which the table is based also contains data from the analysis of several RMs (mussel tissue, lobster hepatopancreas, oyster tissue, peach leaves, and mixed diet) that were digested using HNO₃ in a high-pressure digestion vessel. In general, the results were in good agreement with the certified values. For the determination of V, Cr, Zn, As, and Se, more accurate results were obtained when 8% nitrogen was added to the nebulizer gas flow to reduce polyatomic interferences. The DLs were generally poorer when nitrogen was added (a factor of 10 or less), but were adequate for the multielement determinations.

A very powerful method that can be used with ICP/MS (and any other MS technique) detection is isotope dilution (ID). In ID analysis, the sample is spiked with a known amount of an enriched isotope of the analyte. The altered isotope ratio is then determined in the sample to calculate the amount of analyte present in the original sample. ID is recognized as a definitive analytical method and the accuracy of the method depends on the ability to precisely measure isotope ratios. Since another isotope of the element represents the ideal internal standard, results are expected to be accurate even when nonspectral interferences are present. Park and Suh used ID ICP/MS to determine Cr, Fe, Cd, and Pb in rice flour. For the determination of Fe and Cr, the ICP was operated in the “cool plasma” mode to suppress the background molecular ion intensity (40Ar12C interferes with 52Cr and 40Ar16O interferes with 56Fe). However, because the plasma was less robust, spectral interferences from 40Ca16O and 40Ca16O1H on 56Fe and 57Fe were severe. The Ca was removed from the samples using a microcolumn loaded with 8-hydroxyquinoline. For ID/ICP/MS determinations, the isotopes measured were 52 and 53Cr, 56 and 57Fe, 111 and 112Cd, and 206 and 208Pb. Microwave digestion using HNO₃ only was not adequate for the determination of Fe and Cr in rice flour RMs. An additional treatment with HF and HClO₄ was necessary for quantitative recoveries of Fe and Cr in the samples. DLs (3σ) of 0.003 µg g⁻¹ (0.04 ng mL⁻¹) for Cr, 0.069 µg g⁻¹ (0.92 ng mL⁻¹) for Fe, 0.0003 µg g⁻¹ (0.004 ng mL⁻¹) for Cd, and 0.0003 µg g⁻¹ (0.004 ng mL⁻¹) for Pb were reported.

ETV coupled to ICP/MS has been used for the analysis of slurried food and biological samples. Unlike GFAAS where samples must be vaporized and atomized in the graphite tube, ETV work requires efficient vaporization and subsequent transport of the analyte to the ICP/MS system. Compared with GFAAS, ETV/ICP/MS is more prone to matrix effects (such as space-charge effects and ionization suppression) that result from large amounts of material being introduced to the ICP/MS system. In addition, transport of the analyte from the furnace to the ICP is often enhanced in the presence of the sample matrix, making quantification on the basis of aqueous standards difficult. To deal with these issues, several steps can be taken. Use of internal standardization, ID, and/or addition of a physical carrier.

* 0.5 g of sample (fresh weight) diluted to a final volume of 250 mL for Na, Mg, P, K, and Ca determinations and diluted to 50 mL for the remaining elements.
to the graphite tube can be used to improve the accuracy of ETV/ICP/MS measurements. To ensure the reliability of internal standardization for quantification, an internal standard with a similar mass, ionization potential, and vaporization characteristics compared with the analytes to be determined should be selected. To meet these criteria, several internal standards might have to be used which is both inconvenient and also limits the number of analytes that can be determined. The transient nature of the ETV signal and the scanning nature of quadrupole ICP/MS instruments typically only allow for the determination of no more than five elements (isotopes) simultaneously.

ID can also be used for quantification for elements that have multiple isotopes. Recently, it has been used for the determination of Cu, Zn, Cd, and Pb in marine RMs by slurry ETV/ICP/MS.\(^{(57)}\) Enriched isotopes of \(^{65}\)Cu, \(^{67}\)Zn, \(^{111}\)Cd, and \(^{204}\)Pb were spiked into the slurries as solutions. Samples were charred at 400°C and vaporized at 2300°C for the analyses. Owing to the volatility of Zn and Cd, a modifier (NH\(_4\)NO\(_3\)) was required to stabilize these analytes during the charring step. Determined concentrations of the analytes in three RMs (DORM-2 Dogfish Muscle, DOLT-1 Dogfish Liver, and NIST SRM 1566a Oyster Tissue) were in good agreement with certified values. The precision (%RSD) of the measurements was better than 14% \((n = 7)\). The relatively high RSD values probably resulted from heterogeneity of the materials at the levels analyzed and/or nonrepresentative sampling of the slurry samples. DLs \((3\sigma)\), which were estimated from standard addition curves, were in the range of 5–50 ng g\(^{-1}\) \((0.05–5\) ng mL\(^{-1}\)) for Cu, 200–500 ng g\(^{-1}\) \((2–5\) ng mL\(^{-1}\)) for Zn, 8–20 ng g\(^{-1}\) \((0.08–0.2\) ng mL\(^{-1}\)) for Cd, and 20–50 ng g\(^{-1}\) \((0.2–0.5\) ng mL\(^{-1}\)) for Pb.

Physical carriers such as Pd, C, Mg(NO\(_3\))\(_2\), and NaCl are commonly used to improve analyte transport in ETV/ICP/MS. This principle is identical with what is observed when slurry samples and aqueous samples are compared – enhanced signals are observed with the slurry samples because the sample matrix improves analyte transport. The benefit of using physical carriers for quantification in ETV/ICP/MS is that the transport can be normalized because the physical carrier rather than the sample matrix controls the efficiency of analyte transport, providing similar sensitivities for both aqueous standards and slurry samples. The use of Pd as a physical carrier in quantitative ETV/ICP/MS measurements has been investigated in this laboratory.\(^{(35)}\) When combined with oxygen ashing \((750°C\) for 40 s with 300 mL min\(^{-1}\) air\) for the removal of carbonaceous material, the addition of 1 µg of Pd as a physical carrier allowed the determination of V, Mn, Ni, Cu, and Pb in NIST SRM 1548 Total Diet, SRM 1566a Oyster Tissue and LUTS-1 Lobster Hepatopancreas using aqueous standardization. The use of larger quantities of Pd (up to 10 µg) led to space–charge effects, which reduced the signal intensities by as much as 80%.

### 4 FOOD COMPOSITION LABORATORY METHODS

Techniques and methods used for the determination of elements of nutritional interest in the FCL of the US Department of Agriculture are discussed in this section. Instrumental techniques commonly employed in this laboratory include FAAS, GFAAS, ICP/AES, and ICP/MS. Method selection depends on several factors, including the number of analytes to be determined and the required detection capability. Specific methods for analytes typically measured by each of the techniques are provided.

#### 4.1 Sample Preparation

Both dry and wet ash sample preparations are commonly used in this laboratory. In most instances, either method can be used successfully [e.g. see Miller-Ihli\(^{(38)}\)]; however, there are particular instances where one method is preferred over the other. For example, if large numbers of samples are to be analyzed, wet ashing is preferred because the samples can be simultaneously digested using a heating block. With dry ashing, the muffle furnace can accommodate only a relatively small number of samples at one time. A benefit of dry ashing is that the sample does not have to be diluted as much, offering the potential for greater sensitivity.

##### 4.1.1 Dry Ashing

Approximately 0.5–2 g of homogenized sample is weighed into acid-cleaned quartz or borosilicate tubes and placed in a muffle furnace (Lindberg, Wattertown, WI, USA). The temperature is slowly increased to 480°C and kept there overnight. If the sample ash is white, the sample is diluted to a final volume of 15 mL using 5% v/v sub-boiling distilled HNO\(_3\) (Seastar, Sidney, BC, Canada). If the ash is not white, the sample is treated with 1 mL of concentrated HNO\(_3\), taken to dryness on a heating block and returned to the muffle furnace at 480°C overnight. If necessary, the nitric acid treatment is repeated until a white ash is obtained. The sample ash is diluted to a final volume of 15 mL using 5% v/v sub-boiling distilled HNO\(_3\) (a mixture of 5% v/v HNO\(_3\) and 5% v/v HCl is used for ICP/AES determinations) and stored in acid-cleaned polyethylene test tubes until analyzed. Additional dilutions might be required depending on the analyte and the measurement technique. It should be noted that when analyzing samples by GFAAS, 600 µg
of Mg(NO₃)₂ are added as a modifier (ashing aid) during the dry ashing procedure.

4.1.2 Wet Ashing
Approximately 0.5–2 g of homogenized sample is placed into acid-cleaned silanized quartz or borosilicate tubes and 1–2 mL of water are added to make a slurry. To the slurry, 1 mL of sub-boiling distilled HNO₃ (Seastar) is added. Test tubes are placed on a Multiblock heater (Lab-Line Instruments, Melrose Park, IL, USA) and heated overnight at 80 °C. The next day, samples are treated with 1 mL of 50% H₂O₂ (Fisher, Fairlawn, NJ, USA) added dropwise, and the mixture is heated at 100 °C for 5–6 h. The peroxide treatment is repeated during this time until the digests are clear. The maximum amount of peroxide added should never exceed 5 mL. Digests are then heated overnight at 80 °C. A 1-mL volume of concentrated HCl (Ultrex II, J.T. Baker) is then added to the tube (for improved extraction of Fe) and the mixture is heated at 80 °C for 3–4 h. For GFAAS determinations, HCl is not used because volatile chlorides can form and lead to poor recoveries. Samples are filtered using ashless 7-cm No. 41 filter papers (Whatman, Maidstone, UK), diluted to a final volume of 15 mL using 5% v/v HNO₃ (a mixture of 5% v/v HNO₃ and 5% v/v HCl is used for ICP/AES determinations), and stored in acid-cleaned polyethylene test tubes until analyzed. Additional dilutions might be required depending on the analyte and the measurement technique.

4.2 Flame Atomic Absorption Spectrometry
FAAS determinations are made with a Perkin-Elmer Model 5100 PC spectrophotometer equipped with both a deuterium arc lamp for background correction in the ultraviolet (UV) region (180–300 nm) and a tungsten lamp for background correction in the visible region (300–900 nm). Elements typically measured by FAAS in this laboratory are Ca, Cu, Fe, Mg, Mn, and Zn. An air–acetylene flame is used in all cases. Most often, the FAAS technique is applied only when a small number (≤3) of analytes are being determined, since more rapid multielement techniques (ICP/AES and ICP/MS) are available. Instrumental conditions for FAAS determinations are provided in Table 3. Note that Ca was determined with the use of 8-hydroxyquinoline as a protecting agent to prevent the formation of refractory solute species. No modifiers (releasing agents, ionization suppressors, etc.) are used for the other analytes.

4.3 Graphite Furnace Atomic Absorption Spectrometry
When the detection capabilities of FAAS and ICP/AES are not adequate, GFAAS is frequently used for the trace determination of elements of nutritional interest. Commonly, Cr levels are low (<1 µg g⁻¹) in food samples and require the use of GFAAS. For GFAAS determinations, a Perkin-Elmer 5100 PC spectrophotometer with Zeeman background correction is used. The system includes an AS-60 autosampler and a USS-100 ultrasonic slurry mixer for slurry measurements. Pyrolytic graphite-coated platform-containing tubes are used. Peak-area measurements are used for quantification and calibration is typically performed with aqueous standards. For the analysis of foods and other carbonaceous materials, oxygen ashing is used to remove organic material prior to atomization. Instrumental conditions for the determination of Cr by GFAAS are provided in Table 4.

4.4 Inductively Coupled Plasma Atomic Emission Spectrometry
ICP/AES is routinely used for the determination of a suite of elements (Na, K, Ca, Co, Cu, Cr, Fe, Mg, Mn, Ni, P, V, and Zn) that are of nutritional interest. A typical ICP/AES system is a Leeman Labs (Lowell, MA, USA) PS3000 ICP, which is a combination simultaneous

4.5 Inductively Coupled Plasma Mass Spectrometry

A method for the determination of 13 elements (Na, Mg, P, K, Ca, V, Cr, Fe, Mn, Co, Ni, Zn, and Cu) in food samples using ICP/MS detection has recently been developed in this laboratory.⁵⁹ A Perkin-Elmer SCIEX (Thornhill, ON, Canada) Elan 6000 ICP/MS instrument, equipped with a standard cross-flow nebulizer and Scott-type, double-pass Ryton spray chamber, is used. Operating conditions for the ICP/MS measurements are given in Table 6. Because matrix effects related to high levels of matrix elements can be significant when analyzing food digests (signal suppressions of 50% are common), an internal standard is used. Ga (50 ng mL⁻¹) has proven suitable as an internal standard for the full suite of elements studied. A correction equation for the isobaric interference of ⁴⁰Ca¹⁶O¹H on ⁵⁷Fe is determined. The correction factor is obtained by measuring a 50 µg mL⁻¹ solution of Ca and calculating the ratio of the signals at m/z 60 (⁴⁰Ca¹⁶O¹⁴H) and m/z 43 (Ca). The extent of the CaOH interference is measured at m/z 60 and 43, as opposed to m/z 57 and 40, because of the inability to measure the Ca signal at m/z 40 owing to the very large Ar background. The correction value is typically around 3.5%.

<sup>a</sup> Adjusted to maximize ion signals for 10 \( ng \) mL\(^{-1} \) tuning solution of Mg, Rh, Ce, Ba, and Pb. Adjusted for CeO<sup>2+</sup>/Ce<sup>3+</sup> < 3% and Ba<sup>2+</sup>/Ba<sup>+</sup> < 2%.

<sup>b</sup> Lens scanning (AutoLens<sup>™</sup>) calibration performed with a 10 \( ng \) mL\(^{-1} \) solution of Be, Co, and In containing 25 \( \mu g \) mL\(^{-1} \) of Na, K, and Ca.

<sup>c</sup> Detector cross-calibration (Dual Detector<sup>™</sup> mode) performed using a multielement solution containing levels of analytes that produced signals in pulse counting mode of approximately 200 000–1 000 000 cps (typically 200 ng mL\(^{-1} \) – 2 \( \mu g \) mL\(^{-1} \)).

<sup>d</sup> Standards for minor elements (5–500 ng mL\(^{-1} \)) also contained 30 \( \mu g \) mL\(^{-1} \) of Na, Mg, K, P, and Ca for improved matrix matching.

5 SPECIATION

For essential elements to exert an effect on human health, they must be available from food both for absorption and subsequent utilization by the body (i.e. they must be bioavailable). It is now generally accepted that the total amount of an element present in food tells little of how efficiently it will be absorbed and used. A major influence on the bioavailability of an element is the chemical form or speciation of that particular element. Measurement of chemical speciation can refer to the determination of oxidation states, metal–ligand complexes, and mineral compounds. An excellent overview of methods for trace metal speciation and problems associated with the techniques is given in a book edited by Krull. The combination of chromatographic separation and atomic spectroscopic detection provides a powerful, versatile tool for trace element speciation measurements. In recent years, there have been a large number of publications dealing with chemical speciation measurements in foods and biological samples using chromatography combined with atomic spectroscopy. These include the determination of metal–carbohydrate complexes in fruits and vegetables by size-exclusion high-performance liquid chromatography (HPLC) with ICP/MS detection, multielement speciation of tea infusion using size-exclusion chromatography (SEC) ICP/MS, and Se speciation measurements in enriched garlic, onion, and broccoli samples.

Methods for the speciation of Se compounds have often been described in the literature. Emtteborg et al. developed a method for the separation and detection of selenomethionine, selenite, selenate, and selenocystine using micro bore ion chromatography (IC) coupled to GFAAS. Automated collection of 20-\( \mu L \) fractions in autosampler cups was used for interfacing the chromatographic separation with GFAAS. With a column flow rate of 80 \( \mu L \) min\(^{-1} \), the system provided a time resolution of 15 s, which was adequate for the separation of the selenium compounds. For comparison of chromatographic resolution, IC direct injection nebulization ICP/AES was also used. According to the authors, the trade-off in chromatographic resolution and time consumption in the detection step (approximately 2 min per fraction) using IC/GFAAS was compensated for by a high degree of simplicity and the high specificity and sensitivity of GFAAS. DLs of 2.8–4.1 ng mL\(^{-1} \) (42–61 pg absolute) were reported and the repeatability ranged from 4.3 to 6.2% RSD (n = 4) for the four forms of selenium studied.

Direct coupling of HPLC to ICP/MS is a convenient and sensitive method for Se speciation measurements. As part of a study of Se bioavailability from the human diet, Crews et al. developed an HPLC/ICP/MS method for the determination of Se species in in vitro gastrointestinal extracts of cooked cod. The method used pepsin and HCl (pH 2.0) to simulate gastric digestion in the stomach, and pancreatin, amylase, and bile salts for simulating digestion in the small intestine (pH 6.9). Total Se was measured in cooked cod and in extracts by ICP/MS, following digestion in high-pressure digestion vessels. For speciation measurements, the HPLC effluent was introduced directly to the cross-flow nebulizer of the ICP/MS system at a flow rate of 0.75 \( mL \) min\(^{-1} \). HPLC/ICP/MS allowed the separation of four Se standards (selenomethionine, selenocystine, sodium selenite, and sodium selenate) in less than.
measurements. They play a dominant role in the field of chemical speciation especially very sensitive MS techniques, will certainly refine the role of trace element species in human health can be achieved if standards for that particular form is that quantification of individual species can only be achieved if standards for that particular form are used.

In the future, there is no doubt that the role of speciation measurements in food samples will continue to expand. As analytical methodology is developed and refined to meet the requirements of a particular analysis, the role of trace element species in human health can be more clearly defined. Atomic spectroscopic detection, especially very sensitive MS techniques, will certainly play a dominant role in the field of chemical speciation measurements.

Once the method has been developed it must be validated, ensuring that the method produces data which are in agreement with the “true value” of the analyte in the samples. This is accomplished by doing calibration with method of additions (to check for matrix interference effects) or by running a well-characterized QC material or CRM, to see if the method is producing accurate results. There are several sources of RMs suitable for food analyses, including the International Atomic Energy Agency (IAEA), the National Research Council of Canada (NRCC), and NIST. Perhaps the best known is NIST, which prepares geological, botanical, inorganic, and organic CRMs which they refer to as SRMs and which come with certificates “certifying” specified analyte contents and providing information about the particle size of the material and information on its handling, processing, and packaging.

Table 7 contains data for a wide range of commercial RMs suitable for elemental analyses of food samples. Reference values for as many as 24 elements are available for a total of 34 food-related CRMs, which is a significant improvement compared with 5 years ago. More materials are needed, however, which are more similar to foods as consumed (not freeze-dried) to serve as QC materials for large studies.

Large-scale production of CRMs is very expensive and it is extremely time-consuming to certify a candidate material. In the case of foods, CRMs are needed with certified values for proximates, organic constituents (e.g. vitamins), and also trace elements. Because of the wide range of needs for the variety of analytes of interest, it is typically not feasible to make a single material (e.g. diet material) which will be certified over a wide range of analytes. It does not make sense, for example, to have a single material certified for proximates (ash, fat, and moisture) as well as trace elements because of the cost of certifying a material. It is simply too expensive to justify the use of several grams of a material certified for a range of trace elements to be used for moisture determinations. As a result, it is critical to have a range of suitable CRMs for the variety of analytes of interest.

Most laboratories involved in large-scale studies with hundreds of determinations utilize secondary QC samples for ongoing QC. The CRMs are used for method validation and then in-house QC samples are developed which usually consist of a particularly large amount of an individual sample or several samples that are pooled together. Reference concentrations for the various analytes of interest are typically determined through cooperation with at least one additional laboratory. After being characterized, the QC samples are used in several ways. They may be analyzed in conjunction with unknown samples to verify sample preparation procedures and calibration. QC samples can be labeled or analyzed

12 min with a reproducibility of retention times of better than 5% RSD. The total concentration of Se (measured as $^{82}\text{Se}$) in cooked cod was determined to be $1.52 \pm 0.07 \mu g g^{-1}$ and the amount of Se extracted in the gastric supernatant and gastrointestinal supernatant was 50.5 and 61.3%, respectively. HPLC/ICP/MS analysis of the extract revealed two Se species, selenite and an unidentified form that was believed to be an organic form because of the similarity in retention time to selenomethionine. Approximately 12% of the total Se was present as selenite. It should be noted that the instrumental response (signal per mass of $^{82}\text{Se}$) was species specific: the inorganic forms gave approximately equal responses but the responses for selenomethionine and selenocystine were significantly lower (40 and 55% respectively). The authors suggested that this could be due to either suppression of the Se signal for the organic standards or retention of the Se from the organic standards by the chromatography system. What this means is that quantification of individual species can only be achieved if standards for that particular form are used.

In the future, there is no doubt that the role of speciation measurements in food samples will continue to expand. As analytical methodology is developed and refined to meet the requirements of a particular analysis, the role of trace element species in human health can be more clearly defined. Atomic spectroscopic detection, especially very sensitive MS techniques, will certainly play a dominant role in the field of chemical speciation measurements.

6 QUALITY ASSURANCE, METHOD VALIDATION, AND REFERENCE MATERIALS

General aspects of QA are highlighted here. There are three general aspects to validating analytical data: (1) development of a method of analysis; (2) validation of the method; and (3) ensuring that the method remains valid throughout its use.688 Development of a reliable analytical method requires that the strengths, limitations, and ruggedness of the analytical aspects be documented by appropriate research and development. Potential matrix effects must be identified for each sample matrix. In some instances, interferences are analyte specific requiring that different instrumental parameters or sample preparation methods may be necessary for both different matrices and for different elements. Such analytical variables must be identified and taken into consideration in the development of an accurate analytical procedure.

Values in parentheses are noncertified reference values; values in square brackets are the range of reference values for this material.

---

“blind” (unidentified to the analyst). The results of the QC samples are compared with the predetermined “true” values and poor accuracy or precision typically leads to rejection of the results for samples run in that series.

Accuracy is concerned with correctness. If a measurement process produces the correct results it is considered to be accurate and the measured value is also accurate. The scatter of values reflects the measurement precision (or reproducibility). In setting up a QC program, it is important to focus on both accuracy and precision and have an effective means of measuring both. It has been stated that a measurement is accurate when the reported value does not differ from the true value and that error in reported values occurs as a result of bias and imprecision. An accurate method is one capable of providing precise and unbiased results (within acceptable limits). Accurate and precise are relative terms.

The DL, defined as three times the standard deviation of the blank (3σ), represents the lowest concentration which can be reliably determined (33% RSD) using a particular method. In FCL we prefer to work at a quantitation limit of five times the DL (which provides a measurement precision of 6.6% RSD). Consider that RM 8431 Mixed Diet will be used as a control material for a study using FAAS and that we are interested in Cu and Mn. If a 1-g sample (dry weight) is diluted to 15 mL using a wet ash digestion, the expected solution concentrations will be Cu 0.224 µg mL⁻¹ and Mn and 0.541 µg mL⁻¹. The flame solution DL for both of these elements is 0.001 µg mL⁻¹ [from Welz(37)], so both will be measured well above both the DL and the quantitation limit. It is critical to realize that analyte concentration may not be equivalent for both unknown samples and CRMs, and that unknown samples are seldom as homogeneous as a carefully prepared CRM. Individual analysts and the food composition community in general have committed to further development of both commercial CRMs and in-house QC materials representing a wide range of food matrices (based on proximate content) so that more representative materials are available for QA and QC. Experimental design must take into consideration the statistical information provided by the data so that the analyst can easily determine the confidence they may have in their data.

The original hypothesis on fiber, that a diet with a high content of unrefined plant foods was linked to a low incidence of Western diseases, has been largely confirmed. The plant cell wall encapsulates and thus controls the release of nutrients, including free sugars and starch, from the plant tissue and thereby influences the glycemic response. This ability to influence digestion and absorption, and thus the physiological effects of other nutrients, is an important property of dietary fiber. The other main properties of a high-fiber diet are increased fermentation and fecal bulk, and binding of potentially toxic substances, e.g. lectins, thus affecting large gut physiology and health. Naturally high-fiber diets have low contents of fat and sodium, and are a good source of vitamins and minerals. The national dietary guidelines recommend a diet rich in fruit, vegetables and whole-grain cereals, and thus naturally rich in plant cell-wall material, the major constituents (approximately 90%) of which are nonstarch polysaccharides (NSP). Food labeling for dietary fiber should help the consumer in the choice of the recommended unfortified, high-fiber diet. Analysis of NSP represents a good measure of endogenous plant cell-wall material for most plant foods and NSP values thus provide a very good marker for a high-fiber diet.

The Englyst procedure for the measurement of dietary fiber as NSP involves enzymatic hydrolysis of starch, precipitation of NSP in ethanol, acid hydrolysis of the NSP and measurement of the released constituent sugars by gas–liquid chromatography (GLC), high-performance liquid chromatography (HPLC) or colorimetry. Values for total, soluble and insoluble NSP may be obtained using any of the end-point techniques. The detailed information obtained from the chromatographic methods, which identify and quantify the individual constituent sugars, is particularly useful in studies of the relation between intakes of NSP and health; values for the constituent NSP sugars have been published for a wide range of foods.
1 INTRODUCTION

The original hypothesis on fiber was that a diet with a high content of unrefined plant foods (rich in cell-wall material) was linked to a low incidence of some of the so-called Western diseases.\(^1\) The hypothesis has been largely confirmed and this is the background for the recommendations in national dietary guidelines for the consumption of a diet rich in fruit, vegetables and whole-grain cereals, and thus naturally rich in plant cell-wall material. The major constituents (approximately 90\%) of this material are NSP and, therefore, the plant cell-wall NSP content of foods is a very good marker for the fiber-rich diet recommended in the guidelines. In line with this, in 1994 the EC Scientific Committee for Food stated in a report of their deliberations on the definition of dietary fiber for nutrition labeling:\(^4\)

There was lengthy discussion as to the material that should be defined as fibre for the purposes of nutrition labelling. In particular the inclusion or not of Resistant Starch in the definition of fibre was argued extensively. The Committee decided that the material to be considered as fibre for the purposes of nutrition labelling should be confined to non-starch polysaccharides of cell-wall origin.

and in 1998, the FAO/WHO presented a list of recommendations on the role of carbohydrates in nutrition and stated:\(^5\)
